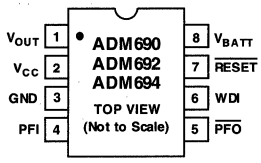
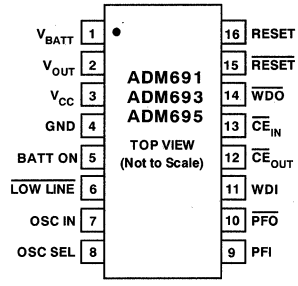
$\overline{WDO}$	Logic Output. The Watchdog Output, $\overline{WDO}$, goes low if WDI remains either high or low for longer than the watchdog timeout period. $\overline{WDO}$ is set high by the next transition at WDI. If WDI is unconnected or at midsupply, the watchdog timer is disabled and $\overline{WDO}$ remains high. $\overline{WDO}$ also goes high when $\overline{LOW\ LINE}$ goes low.

PIN CONFIGURATIONS





PRODUCT SELECTION GUIDE

Part Number	Nominal Reset Time	Nominal V_{CC} Reset Threshold	Nominal Watchdog Timeout Period	Battery Backup Switching	Base Drive Ext PNP	Chip Enable Signals
ADM690	50 ms	4.65 V	1.6 s	Yes	No	No
ADM691	50 ms or ADJ	4.65 V	100 ms, 1.6 s, ADJ	Yes	Yes	Yes
ADM692	50 ms	4.4 V	1.6 s	Yes	No	No
ADM693	50 ms or ADJ	4.4 V	100 ms, 1.6 s, ADJ	Yes	Yes	Yes
ADM694	200 ms	4.65 V	1.6 s	Yes	No	No
ADM695	200 ms or ADJ	4.65 V	100 ms, 1.6 s, ADJ	Yes	Yes	Yes

CIRCUIT INFORMATION

Battery Switchover Section

The battery switchover circuit compares V_{CC} to the V_{BATT} input, and connects V_{OUT} to whichever is higher. Switchover occurs when V_{CC} is 50 mV higher than V_{BATT} as V_{CC} falls, and when V_{CC} is 70 mV greater than V_{BATT} as V_{CC} rises. This 20 mV of hysteresis prevents repeated rapid switching if V_{CC} falls very slowly or remains nearly equal to the battery voltage.

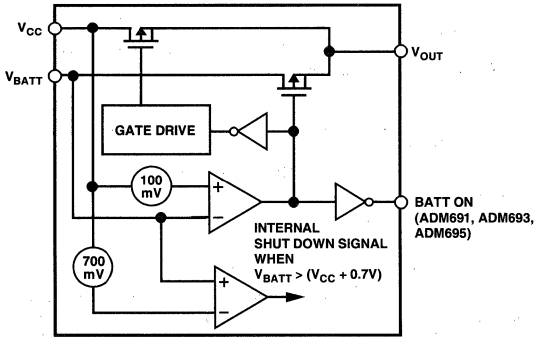


Figure 1. Battery Switchover Schematic

During normal operation with V_{CC} higher than V_{BATT}, V_{CC} is internally switched to V_{OUT} via an internal PMOS transistor switch. This switch has a typical on-resistance of 1.5 Ω and can supply up to 100 mA at the V_{OUT} terminal. V_{OUT} is normally used to drive a RAM memory bank which may require instantaneous currents of greater than 100 mA. If this is the case then a bypass capacitor should be connected to V_{OUT}. The capacitor will provide the peak current transients to the RAM. A capacitance value of 0.1 μF or greater may be used.

If the continuous output current requirement at V_{OUT} exceeds 100 mA or if a lower V_{CC}–V_{OUT} voltage differential is desired, an external PNP pass transistor may be connected in parallel with the internal transistor. The BATT ON output (ADM691/ADM693/ADM695) can directly drive the base of the external transistor.

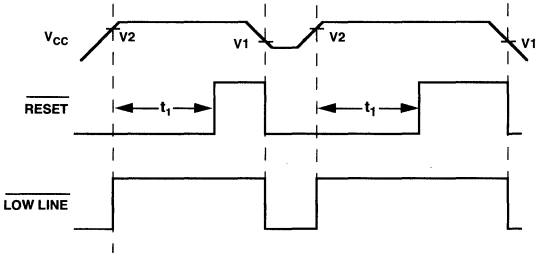
A 20 Ω MOSFET switch connects the V_{BATT} input to V_{OUT} during battery backup. This MOSFET has very low input-to-output differential (dropout voltage) at the low current levels required for battery back up of CMOS RAM or other low power CMOS circuitry. The supply current in battery back up is typically 0.6 μA.

The ADM690/ADM691/ADM694/ADM695 operates with battery voltages from 2.0 V to 4.25 V and the ADM692/ADM693 operates with battery voltages from 2.0 V to 4.0 V. High value capacitors, either standard electrolytic or the farad size double layer capacitors, can also be used for short-term memory back up. A small charging current of typically 10 nA (0.1 μA max) flows out of the V_{BATT} terminal. This current is useful for maintaining rechargeable batteries in a fully charged condition. This extends the life of the back up battery by compensating for its self discharge current. Also note that this current poses no problem when lithium batteries are used for back up since the maximum charging current (0.1 μA) is safe for even the smallest lithium cells.

If the battery-switchover section is not used, V_{BATT} should be connected to GND and V_{OUT} should be connected to V_{CC}.

POWER FAIL $\overline{\text{RESET}}$ OUTPUT

$\overline{\text{RESET}}$ is an active low output which provides a $\overline{\text{RESET}}$ signal to the Microprocessor whenever V_{CC} is at an invalid level. When V_{CC} falls below the reset threshold the $\overline{\text{RESET}}$ output is forced low. The nominal reset voltage threshold is 4.65 V (ADM690/ADM691/ADM694/ADM695) or 4.4 V (ADM692/ADM693).



t_1 = RESET TIME.
V1 = RESET VOLTAGE THRESHOLD LOW
V2 = RESET VOLTAGE THRESHOLD HIGH
HYSTERESIS = V2–V1

Figure 2. Power Fail Reset Timing

On power-up $\overline{\text{RESET}}$ will remain low for 50 ms (200 ms for ADM694 and ADM695) after V_{CC} rises above the appropriate reset threshold. This allows time for the power supply and microprocessor to stabilize. On power-down, the $\overline{\text{RESET}}$ output remains low with V_{CC} as low as 1 V. This ensures that the microprocessor is held in a stable shutdown condition.

This $\overline{\text{RESET}}$ active time is adjustable on the ADM691/ADM693/ADM695 by using an external oscillator or by connecting an external capacitor to the OSC IN pin. Refer to Table I and Figure 4.

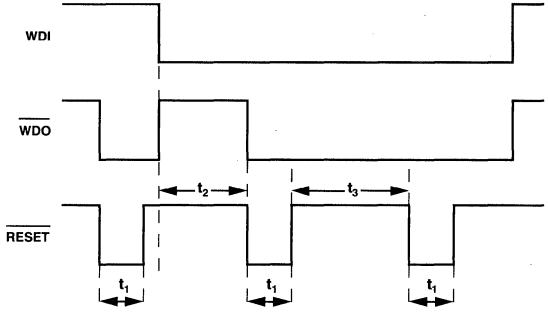
The guaranteed minimum and maximum thresholds of the ADM690/ADM691/ADM694/ADM695 are 4.5 V and 4.73 V, while the guaranteed thresholds of the ADM692/ADM693 are 4.25 V and 4.48 V. The ADM690/ADM691/ADM694/ADM695 is, therefore, compatible with 5 V supplies with a +10%, −5% tolerance while the ADM692/ADM693 is compatible with 5 V ± 10% supplies. The reset threshold comparator has approximately 50 mV of hysteresis. The response time of the reset voltage comparator is less than 1 μs. If glitches are present on the V_{CC} line which could cause spurious reset pulses, then V_{CC} should be decoupled close to the device.

In addition to $\overline{\text{RESET}}$ the ADM691/ADM693/ADM695 contain an active high RESET output. This is the complement of $\overline{\text{RESET}}$ and is intended for processors requiring an active high RESET signal.

Watchdog Timer $\overline{\text{RESET}}$

The watchdog timer circuit monitors the activity of the microprocessor in order to check that it is not stalled in an indefinite loop. An output line on the processor is used to toggle the Watchdog Input (WDI) line. If this line is not toggled within the selected timeout period, a $\overline{\text{RESET}}$ pulse is generated. The nominal watchdog timeout period is preset at 1.6 seconds on the ADM690/ADM692/ADM694. The ADM691/ADM693/ADM695 may be configured for either a fixed "short" 100 ms or a "long" 1.6 second timeout period or for an adjustable timeout period. If the "short" period is selected, some systems may be unable to service the watchdog timer immediately after a reset, so the ADM691/ADM693/ADM695 automatically selects the "long" timeout period directly after a reset is issued. The watchdog timer is restarted at the end of reset, whether the reset was caused by lack of activity on WDI or by V_{CC} falling below the reset threshold.

The normal (short) timeout period becomes effective following the first transition of WDI after $\overline{\text{RESET}}$ has gone inactive. The watchdog timeout period restarts with each transition on the WDI pin. To ensure that the watchdog timer does not time out, either a high-to-low or low-to-high transition on the WDI pin must occur at or less than the minimum timeout period. If WDI remains permanently either high or low, reset pulses will be issued after each "long" timeout period (1.6 s). The watchdog monitor can be deactivated by floating the Watchdog Input (WDI) or by connecting it to midsupply.



t_1 = RESET TIME.
t_2 = NORMAL (SHORT) WATCHDOG TIMEOUT PERIOD.
t_3 = WATCHDOG TIMEOUT PERIOD IMMEDIATELY FOLLOWING A RESET.

Figure 3. Watchdog Timeout Period and Reset Active Time

15

Table I. ADM691, ADM693, ADM695 Reset Pulse Width and Watchdog Timeout Selections

OSC SEL	OSC IN	Watchdog Timeout Period		Reset Active Period	
		Normal	Immediately After Reset	ADM691/ADM693	ADM695
Low	External Clock Input	1024 CLKS	4096 CLKS	512 CLKS	2048 CLKS
Low	External Capacitor	400 ms × C/47 pF	1.6 s × C/47 pF	200 ms × C/47 pF	800 ms × C/47 pF
Floating or High	Low	100 ms	1.6 s	50 ms	200 ms
Floating or High	Floating or High	1.6 s	1.6 s	50 ms	200 ms

NOTE
With the OSC SEL pin low, OSC IN can be driven by an external clock signal, or an external capacitor can be connected between OSC IN and GND. The nominal internal oscillator frequency is 10.24 kHz. The nominal oscillator frequency with external capacitor is: F_{OSC} (Hz) = 184,000/C (pF).

The watchdog timeout period is fixed at 1.6 seconds, and the reset pulse width is fixed at 50 ms on the ADM690/ADM692. On the ADM694 the watchdog timeout period is also 1.6 seconds but the reset pulse width is fixed at 200 ms. The ADM691/ADM693/ADM695 allow these times to be adjusted as shown in Table I. Figure 4 shows the various oscillator configurations which can be used to adjust the reset pulse width and watchdog timeout period.

The internal oscillator is enabled when OSC SEL is high or floating. In this mode, OSC IN selects between the 1.6 second and 100 ms watchdog timeout periods. With OSC IN connected high or floating, the 1.6 second timeout period is selected; while with it connected low, the 100 ms timeout period is selected. In either case, immediately after a reset, the timeout period is 1.6 seconds. This gives the microprocessor time to reinitialize the system. If OSC IN is low, then the 100 ms watchdog period becomes effective after the first transition of WDI. The software should be written such that the I/0 port driving WDI is left in its power-up reset state until the initialization routines are completed and the microprocessor is able to toggle WDI at the minimum watchdog timeout period of 70 ms.

Watchdog Output (WDO)
The Watchdog Output $\overline{WDO}$ (ADM691/ADM693/ADM695) provides a status output which goes low if the watchdog timer "times out" and remains low until set high by the next transition on the Watchdog Input. $\overline{WDO}$ is also set high when V_{CC} goes below the reset threshold.

$\overline{CE}$ Gating and RAM Write Protection (ADM691/ADM693/ADM695)

The ADM691/ADM693/ADM695 products include memory protection circuitry which ensures the integrity of data in memory by preventing write operations when V_{CC} is at an invalid level. There are two additional pins, $\overline{CE}_{IN}$ and $\overline{CE}_{OUT}$, which may be used to control the Chip Enable or Write inputs of CMOS RAM. When V_{CC} is present, $\overline{CE}_{OUT}$ is a buffered replica of $\overline{CE}_{IN}$, with a 5 ns propagation delay. When V_{CC} falls below the reset voltage threshold or V_{BATT}, an internal gate forces $\overline{CE}_{OUT}$ high, independent of $\overline{CE}_{IN}$.

$\overline{CE}_{OUT}$ typically drives the $\overline{CE}$, $\overline{CS}$, or write input of battery backed up CMOS RAM. This ensures the integrity of the data in memory by preventing write operations when V_{CC} is at an invalid level. Similar protection of EEPROMs can be achieved by using the $\overline{CE}_{OUT}$ to drive the store or write inputs.

If the 5 ns typical propagation delay of $\overline{CE}_{OUT}$ is excessive, connect $\overline{CE}_{IN}$ to GND and use the resulting $\overline{CE}_{OUT}$ to control a high speed external logic gate.

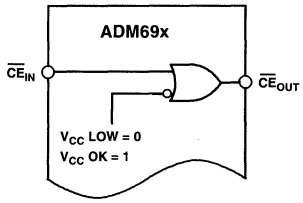

Figure 5. Chip Enable Gating

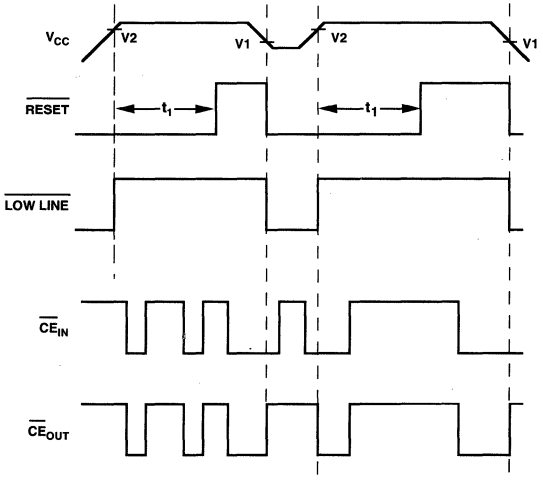

Figure 6. Chip Enable Timing

Power Fail Warning Comparator

An additional comparator is provided for early warning of failure in the microprocessor's power supply. The Power Fail Input (PFI) is compared to an internal +1.3 V reference. The Power Fail Output ($\overline{PFO}$) goes low when the voltage at PFI is less than 1.3 V. Typically PFI is driven by an external voltage divider which senses either the unregulated dc input to the system's 5 V regulator or the regulated 5 V output. The voltage divider ratio can be chosen such that the voltage at PFI falls below 1.3 V several milliseconds before the +5 V power supply falls below the reset threshold. $\overline{PFO}$ is normally used to interrupt the microprocessor so that data can be stored in RAM and the shut down procedure executed before power is lost.

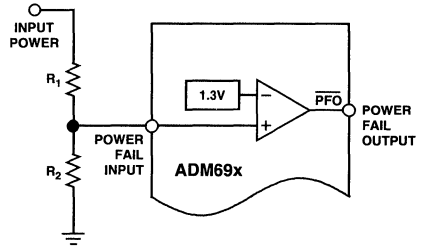

Figure 7. Power Fail Comparator

Table II. Input and Output Status In Battery Backup Mode

Signal	Status
V_{OUT}	V_{OUT} is connected to V_{BATT} via an internal PMOS switch.
$\overline{RESET}$	Logic low.
RESET	Logic high. The open circuit output voltage is equal to V_{OUT}.
$\overline{LOW\ LINE}$	Logic low.
BATT ON	Logic high. The open circuit voltage is equal to V_{OUT}.
WDI	WDI is ignored. It is internally disconnected from the internal pull-up resistor and does not source or sink current as long as its input voltage is between GND and V_{OUT} The input voltage does not affect supply current.
$\overline{WDO}$	Logic high. The open circuit voltage is equal to V_{OUT}.
PFI	The Power Fail Comparator is turned off and has no effect on the Power Fail Output.
$\overline{PFO}$	Logic low.
$\overline{CE}_{IN}$	$\overline{CE}_{IN}$ is ignored. It is internally disconnected from its internal pull-up and does not source or sink current as long as its input voltage is between GND and V_{OUT}. The input voltage does not affect supply current.
$\overline{CE}_{OUT}$	Logic high. The open circuit voltage is equal to V_{OUT}.
OSC IN	OSC IN is ignored.
OSC SEL	OSC SEL is ignored.

Microprocessor Supervisory Circuits

ADM696/ADM697

FEATURES

Superior Upgrade for MAX696/MAX697
Specified Over Temperature
Adjustable Low Line Voltage Monitor
Power OK/Reset Time Delay
Reset Assertion Down to 1 V V_{CC}
Watchdog Timer—100 ms, 1.6 s, or Adjustable
Low Switch On Resistance
1.5 Ω Normal, 20 Ω in Backup
600 nA Standby Current
Automatic Battery Backup Switching (ADM696)
Fast On-Board Gating of Chip Enable Signals (ADM697)
Voltage Monitor for Power Fail or Low Battery Warning

APPLICATIONS

Microprocessor Systems
Computers
Controllers
Intelligent Instruments
Automotive Systems
Critical μP Power Monitoring

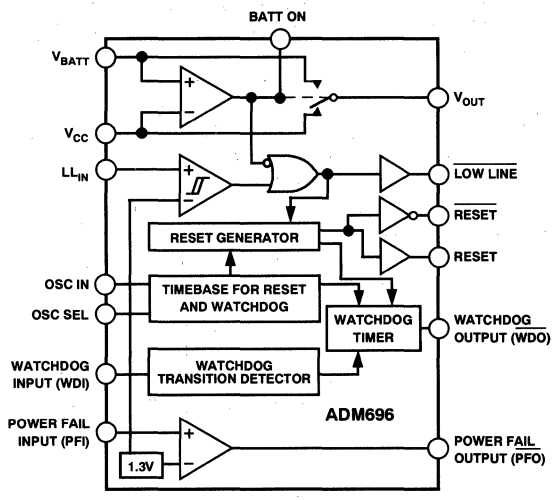
GENERAL DESCRIPTION

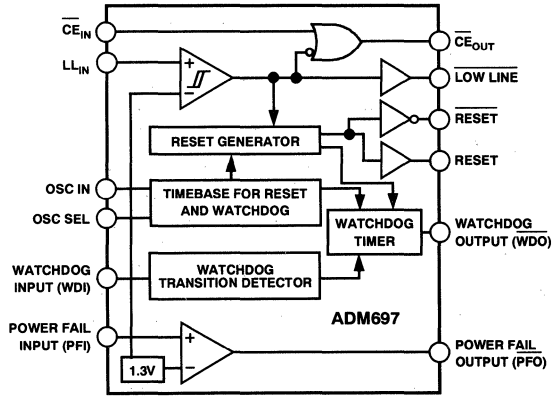
The ADM696/ADM697 supervisory circuits offer complete single chip solutions for power supply monitoring and battery control functions in microprocessor systems. These functions include μP reset, backup-battery switchover, watchdog timer, CMOS RAM write protection, and power failure warning.

The ADM696/ADM697 are available in 16-pin DIP and small outline packages and provide the following functions:

1. Power-On Reset output during power-up, power-down and brownout conditions. The RESET voltage threshold is adjustable using an external voltage divider. The $\overline{\text{RESET}}$ output remains operational with V_{CC} as low as 1 V.
2. A Reset pulse if the optional watchdog timer has not been toggled within a specified time.
3. Separate watchdog timeout and low line status outputs.
4. Adjustable reset and watchdog timeout periods.
5. A 1.3 V threshold detector for power fail warning, low battery detection, or to monitor a power supply other than V_{CC}.
6. Battery backup switching for CMOS RAM, CMOS microprocessor or other low power logic (ADM696).
7. Write protection of CMOS RAM or EEPROM (ADM697).

FUNCTIONAL BLOCK DIAGRAMS





The ADM696/ADM697 is fabricated using an advanced epitaxial CMOS process combining low power consumption (5 mW), extremely fast Chip Enable gating (5 ns) and high reliability. $\overline{\text{RESET}}$ assertion is guaranteed with V_{CC} as low as 1 V. In addition, the power switching circuitry is designed for minimal voltage drop thereby permitting increased output current drive of up to 100 mA without the need for an external pass transistor.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

SPECIFICATIONS (V_{CC} = Full Operating Range, V_{BATT} = +2.8 V, T_A = T_{MIN} to T_{MAX} unless otherwise noted.)

Parameter	Min	Typ	Max	Units	Test Conditions/Comments
V_{CC} Operating Voltage Range	3.0		5.5	V	
V_{BATT} Operating Voltage Range	2.0		V_{CC} – 0.3	V	
BATTERY BACKUP SWITCHING (ADM696)					
V_{OUT} Output Voltage	V_{CC} – 0.05	V_{CC} – 0.025		V	I_{OUT} = 1 mA
	V_{CC} – 0.5	V_{CC} – 0.25		V	I_{OUT} ≤ 100 mA
V_{OUT} in Battery Backup Mode	V_{BATT} – 0.05	V_{BATT} – 0.02		V	I_{OUT} = 250 µA, V_{CC} < V_{BATT} – 0.2 V
Supply Current (excludes I_{OUT})		1	1.95	mA	I_{OUT} = 100 mA
Supply Current in Battery Backup Mode		0.6	1	µA	V_{CC} = 0 V, V_{BATT} = 2.8 V
Battery Standby Current					5.5 V > V_{CC} > V_{BATT} + 0.2 V

*Stresses above those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. This is a stress rating only and functional operation of the device at these or any other conditions above those listed in the operational sections of this specification is not implied. Exposure to absolute maximum ratings for extended periods of time may affect device reliability.

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the AD696/ADM697 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

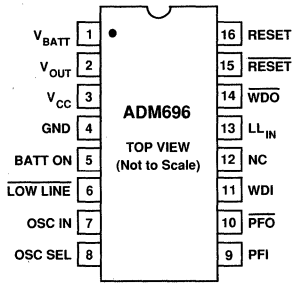
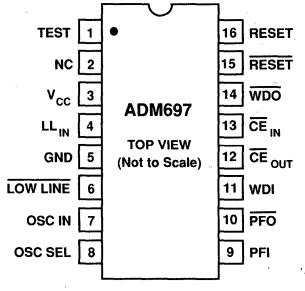
PIN CONFIGURATIONS





PIN FUNCTION DESCRIPTION

Mnemonic	Pin No. ADM696	Pin No. ADM697	Function
V_{CC}	3	3	Power Supply Input +3 V to +5 V.
V_{BATT}	1	—	Backup Battery Input. Connect to Ground if a backup battery is not used.
V_{OUT}	2	—	Output Voltage, V_{CC} or V_{BATT} is internally switched to V_{OUT} depending on which is at the highest potential. V_{OUT} can supply up to 100 mA to power CMOS RAM. Connect V_{OUT} to V_{CC} if V_{OUT} and V_{BATT} are not used.
GND	4	5	0 V. Ground reference for all signals.
$\overline{RESET}$	15	15	Logic Output. $\overline{RESET}$ goes low whenever LL_{IN} falls below 1.3 V or when V_{CC} falls below the V_{BATT} input voltage. $\overline{RESET}$ remains low for 50 ms after LL_{IN} goes above 1.3 V, $\overline{RESET}$ also goes low for 50 ms if the watchdog timer is enabled but not serviced within its timeout period. The $\overline{RESET}$ pulse width can be adjusted as shown in Table I.
WDI	11	11	Watchdog Input, WDI is a three level input. If WDI remains either high or low for longer than the watchdog timeout period, $\overline{RESET}$ pulses low and $\overline{WDO}$ goes low. The timer resets with each transition at the WDI input. The watchdog timer is disabled when WDI is left floating or is driven to midsupply.
PFI	9	9	Power Fail Input. PFI is the noninverting input to the Power Fail Comparator when PFI is less than 1.3 V, PFO goes low. Connect PFI to GND or V_{OUT} when not used. See Figure 1.
$\overline{PFO}$	10	10	Power Fail Output. $\overline{PFO}$ is the output of the Power Fail Comparator. It goes low when PFI is less than 1.3 V. The comparator is turned off and $\overline{PFO}$ goes low when V_{CC} is below V_{BATT}.
$\overline{CE}_{IN}$	—	13	Logic Input. The input to the CE gating circuit. Connect to GND or V_{OUT} if not used.
$\overline{CE}_{OUT}$	—	12	Logic Output. $\overline{CE}_{OUT}$ is a gated version of the $\overline{CE}_{IN}$ signal. $\overline{CE}_{OUT}$ tracks $\overline{CE}_{IN}$ when LL_{IN} is above 1.3 V. If LL_{IN} is below 1.3 V, $\overline{CE}_{OUT}$ is forced high.
BATT ON	5	—	Logic Output. BATT ON goes high when V_{OUT} is internally switched to the V_{BATT} input. It goes low when V_{OUT} is internally switched to V_{CC}. The output typically sinks 7 mA and can directly drive the base of an external PNP transistor to increase the output current above the 100 mA rating of V_{OUT}.
$\overline{LOW\ LINE}$	6	6	Logic Output. $\overline{LOW\ LINE}$ goes low when LL_{IN} falls below 1.3 V. It returns high as soon as LL_{IN} rises above 1.3 V
RESET	16	16	Logic Output. RESET is an active high output. It is the inverse of $\overline{RESET}$.
OSC SEL	8	8	Logic Oscillator Select Input. When OSC SEL is unconnected or driven high, the internal oscillator sets the reset time delay and watchdog timeout period. When OSC SEL is low, the external oscillator input, OSC IN, is enabled. OSC SEL has a 3 μA internal pullup. See Table I and Figure 4.
OSC IN	7	7	Logic Oscillator Input. When OSC SEL is low, OSC IN can be driven by an external clock to adjust both the reset delay and the watchdog timeout period. The timing can also be adjusted by connecting an external capacitor to this pin. See Table I and Figure 4. When OSC SEL is high or floating, OSC IN selects between fast and slow watchdog timeout periods.
$\overline{WDO}$	14	14	Logic Output. The Watchdog Output, $\overline{WDO}$, goes low if WDI remains either high or low for longer than the watchdog timeout period. $\overline{WDO}$ is set high by the next transition at WDI. If WDI is unconnected or at midsupply, $\overline{WDO}$ remains high. $\overline{WDO}$ also goes high when $\overline{LOW\ LINE}$ goes low.
NC	12	2	No Connect. It should be left open.
LL_{IN}	13	4	Voltage Sensing Input. The voltage on the low line input, LLIN, is compared with a 1.3 V reference voltage. This input is normally used to monitor the power supply voltage. The output of the comparator generates a $\overline{LOW\ LINE}$ output signal. It also generates a RESET/$\overline{RESET}$ output.
TEST	—	1	This is a special test pin using during device manufacture. It should be connected to GND.

CIRCUIT INFORMATION

Battery-Switchover Section (ADM696)

The battery switchover circuit compares V_{CC} to the V_{BATT} input, and connects V_{OUT} to whichever is higher. Switchover occurs when V_{CC} is 50 mV higher than V_{BATT} as V_{CC} falls, and when V_{CC} is 70 mV greater than V_{BATT} as V_{CC} rises. This 20 mV of hysteresis prevents repeated rapid switching if V_{CC} falls very slowly or remains nearly equal to the battery voltage.

During normal operation with V_{CC} higher than V_{BATT}, V_{CC} is internally switched to V_{OUT} via an internal PMOS transistor switch. This switch has a typical on resistance of 1.5 Ω and can supply up to 100 mA at the V_{OUT} terminal. V_{OUT} is normally used to drive a RAM memory bank which may require instantaneous currents of greater than 100 mA. If this is the case, then a bypass capacitor should be connected to V_{OUT}. The capacitor will provide the peak current transients to the RAM. A capacitance value of 0.1 µF or greater may be used.

If the continuous output current requirement at V_{OUT} exceeds 100 mA or if a lower V_{CC}–V_{OUT} voltage differential is desired, an external PNP pass transistor may be connected in parallel with the internal transistor. The BATT ON output can directly drive the base of the external transistor.

A 20 Ω MOSFET switch connects the V_{BATT} input to V_{OUT} during battery backup. This MOSFET has very low input-to-output differential (dropout voltage) at the low current levels required for battery backup of CMOS RAM or other low power CMOS circuitry. The supply current in battery backup is typically 0.6 µA.

The ADM696 operates with battery voltages from 2.0 V to V_{CC} −0.3 V). High value capacitors, either standard electrolytic or the farad-size double layer capacitors, can also be used for short-term memory backup. A small charging current of typically 10 nA (0.1 µA max) flows out of the V_{BATT} terminal. This current is useful for maintaining rechargeable batteries in a fully charged condition. This extends the life of the backup battery by compensating for its self discharge current. Also note that this current poses no problem when lithium batteries are used for backup since the maximum charging current (0.1 µA) is safe for even the smallest lithium cells.

If the battery-switchover section is not used, V_{BATT} should be connected to GND and V_{OUT} should be connected to V_{CC}.

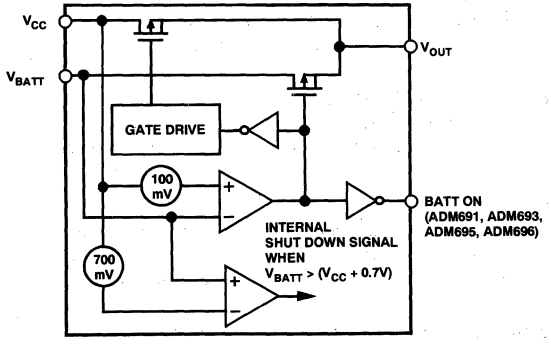


Figure 1. Battery Switchover Schematic

Low Line $\overline{\text{RESET}}$ OUTPUT

$\overline{\text{RESET}}$ is an active low output which provides a $\overline{\text{RESET}}$ signal to the microprocessor whenever the Low Line Input (LL_{IN}) is below 1.3 V. The LL_{IN} input is normally used to monitor the power supply voltage. An internal timer holds $\overline{\text{RESET}}$ low for 50ms after the voltage on LL_{IN} rises above 1.3 V. This is intended as a power-on $\overline{\text{RESET}}$ signal for the processor. It allows time for the power supply and microprocessor to stabilize. On power-down, the $\overline{\text{RESET}}$ output remains low with V_{CC} as low as 1 V. This ensures that the microprocessor is held in a stable shutdown condition.

The LL_{IN} comparator has approximately 12 mV of hysteresis for enhanced noise immunity.

In addition to $\overline{\text{RESET}}$, an active high RESET output is also available. This is the complement of $\overline{\text{RESET}}$ and is useful for processors requiring an active high RESET.

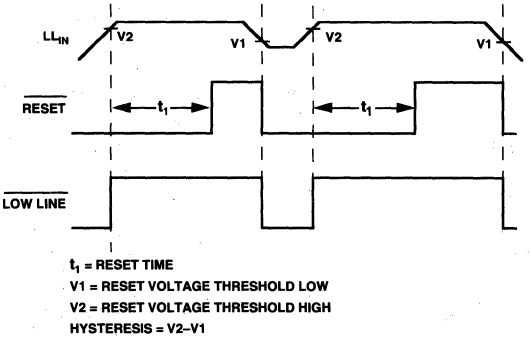

Figure 2. Power-Fail Reset Timing

Watchdog Timer $\overline{\text{RESET}}$

The watchdog timer circuit monitors the activity of the microprocessor in order to check that it is not stalled in an indefinite loop. An output line on the processor is used to toggle the Watchdog Input (WDI) line. If this line is not toggled within the selected timeout period, a $\overline{\text{RESET}}$ pulse is generated. The ADM696/ADM697 may be configured for either a fixed "short" 100 ms or a "long" 1.6 second timeout period or for an adjustable timeout period. If the "short" period is selected some systems may be unable to service the watchdog timer immediately after a reset, so a "long" timeout is automatically initiated directly after a reset is issued. The watchdog timer is restarted at the end of Reset, whether the Reset was caused by lack of activity on WDI or by LL_{IN} falling below the reset threshold.

The normal (short) timeout period becomes effective following the first transition of WDI after $\overline{\text{RESET}}$ has gone inactive. The watchdog timeout period restarts with each transition on the WDI pin. To ensure that the watchdog timer does not time out, either a high-to-low or low-to high transition on the WDI pin must occur at or less than the minimum timeout period. If WDI remains permanently either high or low, reset pulses will be issued after each timeout period (1.6 s). The watchdog monitor can be deactivated by floating the Watchdog Input (WDI) or by connecting it to midsupply.

Table I. ADM696, ADM697 Reset Pulse Width and Watchdog Timeout Selections

OSC SEL	OSC IN	Watchdog Timeout Period		Reset Active Period
		Normal	Immediately After Reset	
Low	External Clock Input	1024 CLKS	4096 CLKS	512 CLKS
Low	External Capacitor	400 ms × C/47 pF	1.6 s × C/47 pF	200 ms × C/47 pF
Floating or High	Low	100 ms	1.6 s	50 ms
Floating or High	Floating or High	1.6 s	1.6 s	50 ms

NOTE
With the OSC SEL pin low, OSC IN can be driven by an external clock signal, or an external capacitor can be connected between OSC IN and GND. The nominal internal oscillator frequency is 10.24 kHz. The nominal oscillator frequency with external capacitor is: F_{OSC} (Hz) = 184,000/C (pF).

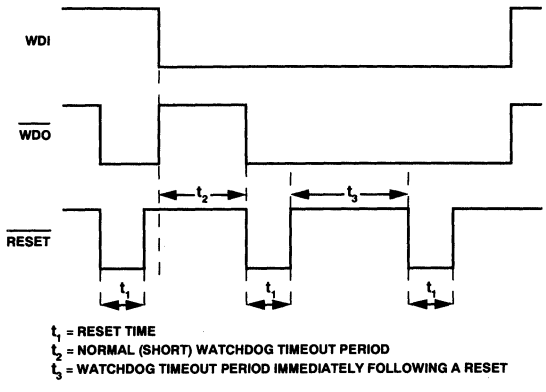

Figure 3. Watchdog Timeout Period and Reset Active Time

The watchdog timeout period defaults to 1.6 s and the reset pulse width defaults to 50 ms but these times to be adjusted as shown in Table I. Figure 4 shows the various oscillator configurations which can be used to adjust the reset pulse width and watchdog timeout period.

The internal oscillator is enabled when OSC SEL is high or floating. In this mode, OSC IN selects between the 1.6 second and 100 ms watchdog timeout periods. In either case, immediately after a reset the timeout period is 1.6 s. This gives the microprocessor time to reinitialize the system. If OSC IN is low, then the 100 ms watchdog period becomes effective after the first transition of WDI. The software should be written such that the I/O port driving WDI is left in its power-up reset state until the initialization routines are completed and the microprocessor is able to toggle WDI at the minimum watchdog timeout period of 70 ms.

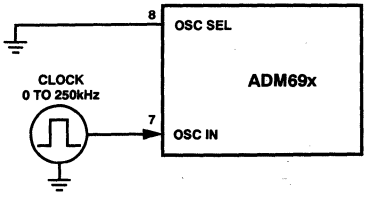

Figure 4a. External Clock Source

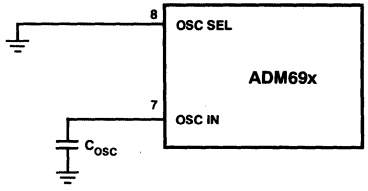

Figure 4b. External Capacitor

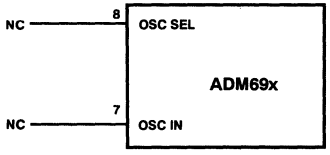

Figure 4c. Internal Oscillator (1.6 s Watchdog)

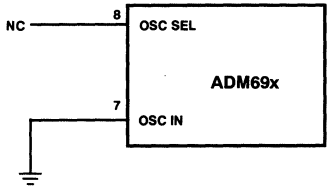

Figure 4d. Internal Oscillator (100 ms Watchdog)

Watchdog Output ($\overline{WDO}$)
The Watchdog Output $\overline{WDO}$ provides a status output which goes low if the watchdog timer "times out" and remains low until set high by the next transition on the watchdog input. $\overline{WDO}$ is also set high when LL_{IN} goes below the reset threshold.

15

CE Gating and RAM Write Protection (ADM697)
The ADM697 contains memory protection circuitry which ensures the integrity of data in memory by preventing write operations when LL_{IN} is below the threshold voltage. When LL_{IN} is greater than 1.3 V, $\overline{CE}_{OUT}$ is a buffered replica of $\overline{CE}_{IN}$, with a 5 ns propagation delay. When LL_{IN} falls below the 1.3 V threshold, an internal gate forces $\overline{CE}_{OUT}$ high, independent of $\overline{CE}_{IN}$.

$\overline{CE}_{OUT}$ typically drives the CE, CS, or Write input of battery backed up CMOS RAM. This ensures the integrity of the data in memory by preventing write operations when V_{CC} is at an invalid level.

If the 5 ns typical propagation delay of $\overline{CE}_{OUT}$ is excessive, connect $\overline{CE}_{IN}$ to GND and use the resulting $\overline{CE}_{OUT}$ to control a high speed external logic gate.

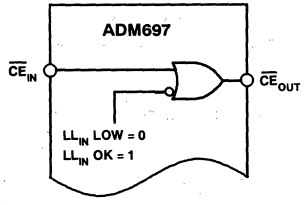

Figure 5. Chip Enable Gating

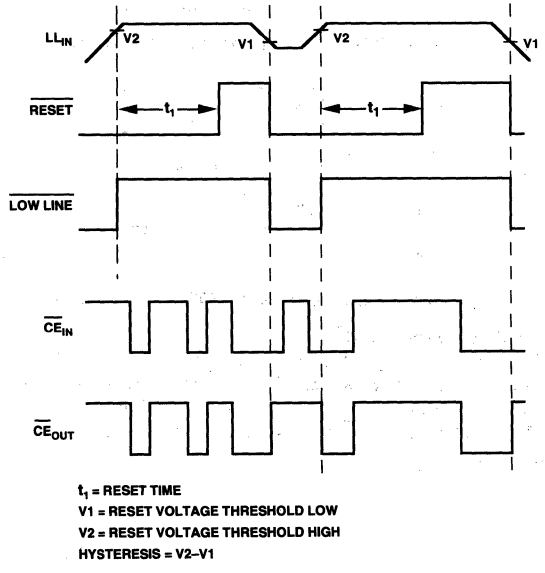

Figure 6. Chip Enable Timing

Power Fail Warning Comparator
An additional comparator is provided for early warning of failure in the microprocessor's power supply. The Power Fail Input (PFI) is compared to an internal +1.3 V reference. The Power Fail Output ($\overline{PFO}$) goes low when the voltage at PFI is less than 1.3 V. Typically PFI is driven by an external voltage divider which senses either the unregulated dc input to the system's 5 V regulator or the regulated 5 V output. The voltage divider ratio can be chosen such that the voltage at PFI falls below 1.3 V several milliseconds before the +5 V power supply falls below the reset threshold. $\overline{PFO}$ is normally used to interrupt the microprocessor so that data can be stored in RAM and the shut-down procedure executed before power is lost.

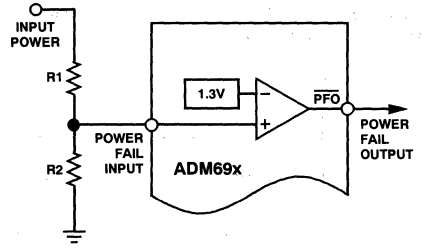

Figure 7. Power Fail Comparator

Table II. Input and Output Status In Battery Backup Mode

Signal	Status
V_{OUT}	(ADM696) V_{OUT} is connected to V_{BATT} via an internal PMOS switch.
$\overline{RESET}$	Logic low.
RESET	Logic high. The open circuit output voltage is equal to V_{OUT}.
$\overline{LOW\ LINE}$	Logic low.
BATT ON	(ADM696) Logic high. The open circuit voltage is equal to V_{OUT}.
WDI	WDI is ignored. It is internally disconnected from the internal pullup resistor and does not source or sink current as long as its input voltage is between GND and V_{OUT}. The input voltage does not affect supply current.
$\overline{WDO}$	Logic high. The open circuit voltage is equal to V_{OUT}.
PFI	The Power Fail Comparator is turned off and has no effect on the Power Fail Output.
$\overline{PFO}$	Logic low.
$\overline{CE}_{IN}$	$\overline{CE}_{IN}$ is ignored. It is internally disconnected from its internal pullup and does not source or sink current as long as its input voltage is between GND and V_{OUT}. The input voltage does not affect supply current.
$\overline{CE}_{OUT}$	Logic high. The open circuit voltage is equal to V_{OUT}.
OSC IN	OSC IN is ignored.
OSC SEL	OSC SEL is ignored.

Critical µP Power Monitoring

GENERAL DESCRIPTION

The ADM698/ADM699 supervisory circuits provide power supply monitoring and watchdog timing for microprocessor systems.

The ADM698 monitors the 5 V V_{CC} power supply and generates a $\overline{\text{RESET}}$ pulse during power up, power down and during low voltage "Brown Out" conditions. The $\overline{\text{RESET}}$ output is guaranteed to be functional (logic low) with V_{CC} as low as 1 V.

The ADM699 features an identical monitoring circuit as in the ADM698 plus an additional watchdog timer input to monitor microprocessor activity. The $\overline{\text{RESET}}$ output is forced low if the watchdog input is not toggled within the 1 second watchdog timeout period.

Both parts are available in 8-pin plastic DIP and 16-lead SOIC packages. The 16-lead SOIC contains additional outputs RESET (without inversion) and Watchdog Output $\overline{\text{WDO}}$ (ADM699 only).

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the ADM698/ADM699 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

PIN FUNCTION DESCRIPTION

Mnemonic	Function
V_{CC}	+5 V Power Supply Input.
GND	0 V. Ground reference for all signals.
$\overline{RESET}$	Logic Output. $\overline{RESET}$ goes low whenever V_{CC} falls below the reset voltage threshold (4.65 V typ). $\overline{RESET}$ remains low for a minimum of 140 ms after V_{CC} returns to 5 V. $\overline{RESET}$ also goes low for a minimum of 140 ms if the watchdog timer is enabled but not serviced within its timeout period.
WDI	Watchdog Input. WDI is a three level input. If WDI remains either high or low for longer than the watchdog timeout period, $\overline{RESET}$ pulses low and $\overline{WDO}$ goes low. The timer resets with each transition on the WDI line. The watchdog timer may be disabled if WDI is left floating or is driven to midsupply.
RESET	(SOIC packages only) Logic Output. RESET is an active high output. It is the inverse of $\overline{RESET}$.
$\overline{WDO}$	(SOIC ADM699 only) Logic Output. The Watchdog Output, $\overline{WDO}$, goes low if WDI remains either high or low for longer than the watchdog timeout period. $\overline{WDO}$ is set high by the next transition at WDI. If WDI is unconnected or at midsupply, the watchdog timer is disabled and $\overline{WDO}$ remains high.

CIRCUIT INFORMATION

Power Fail RESET

A precision voltage detector monitors V_{CC} and generates a $\overline{\text{RESET}}$ output to hold the microprocessor's Reset line low when V_{CC} falls below the reset threshold (4.65 V) (see Figure 4). The reset voltage threshold is set to accommodate a 5% variation on V_{CC}. The voltage detector has 40 mV hysteresis to ensure that glitches on V_{CC} do not activate the $\overline{\text{RESET}}$ output.

On power up, an internal monostable holds $\overline{\text{RESET}}$ low for 140 ms after V_{CC} rises above the reset threshold. This allows the power supply to stabilize on power up and also prevents repeated toggling of $\overline{\text{RESET}}$ even if the 5 V power drops out and recovers with each power line cycle. In order to prevent mistriggering due to transient voltage spikes, it is recommended that a 0.1 μF capacitor be connected at the V_{CC} pin.

The $\overline{\text{RESET}}$ output is guaranteed to remain low with V_{CC} as low as 1 V. This holds the microprocessor in a stable shutdown condition as the power supply comes up.

On the 16-lead SOIC package, an active high RESET output is also provided. This is the complement of $\overline{\text{RESET}}$ and is intended for microprocessors requiring an active high signal.

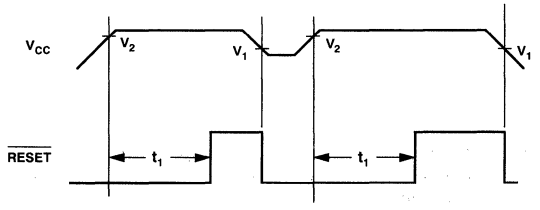

Figure 4. Watchdog Timeout Period vs. Temperature

Watchdog Timer (ADM699 Only)

The watchdog timer input (WDI) monitors an I/O line from the μP system. The μP must toggle this input once every 1.6 seconds to verify correct software execution. Failure to toggle the line indicates that the μP system is not correctly executing its program and may be tied up in an endless loop. If this happens, a reset pulse is generated to initialize the processor.

The WDI input is a three level input and will recognize a low-to- high or a high-to-low transition on its input. The watchdog timer is reset by each WDI transition and then begins its time-out period. If the WDI pin remains either high or low, reset pulses will be issued every 1.6 seconds typically. If the watchdog timer is not needed, the WDI input should be left floating.

The Watchdog Output ($\overline{\text{WDO}}$) (SOIC package Only) provides watchdog status information. It is driven low if WDI is not toggled within the watchdog timeout period. It goes high at the next WDI transition. It is also set high when V_{CC} falls below the reset threshold.

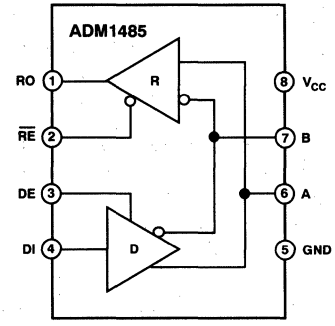
+5 V Low Power EIA RS-485 Transceiver

ADM1485

FEATURES
Meets EIA RS-485 Standard
30 Mb/s Data Rate
Single +5 V Supply
−7 V to +12 V Bus Common-Mode Range
High Speed, Low Power BiCMOS
Thermal Shutdown Protection
Short Circuit Protection
Zero Skew Driver
Driver Propagation Delay: 10 ns
Receiver Propagation Delay: 25 ns
High Z Outputs with Power Off
Superior Upgrade for LTC1485

APPLICATIONS
Low Power RS-485 Systems
DTE-DCE Interface
Packet Switching
Local Area Networks
Data Concentration
Data Multiplexers
Integrated Services Digital Network (ISDN)

FUNCTIONAL BLOCK DIAGRAM



DESCRIPTION

The ADM1485 is a differential line transceiver suitable for high speed bidirectional data communication on multipoint bus transmission lines. It is designed for balanced data transmission and complies with both EIA Standards RS-485 and RS-422. The part contains a differential line driver and a differential line receiver. Both the driver and the receiver may be enabled independently. When disabled, the outputs are tristated.

The ADM1485 operates from a single +5 V power supply. Excessive power dissipation caused by bus contention or by output shorting is prevented by a thermal shutdown circuit. This feature forces the driver output into a high impedance state if during fault conditions a significant temperature increase is detected in the internal driver circuitry.

Up to 32 transceivers may be connected simultaneously on a bus, but only one driver should be enabled at any time. It is important therefore that the remaining disabled drivers do not load the bus. To ensure this, the ADM1485 driver features high output impedance when disabled and also when powered down. This minimizes the loading effect when the transceiver is not being utilized. The high impedance driver output is maintained over the entire common-mode voltage range from −7 V to +12 V.

The receiver contains a fail safe feature which results in a logic high output state if the inputs are unconnected (floating).

The ADM1485 is fabricated on BiCMOS, an advanced mixed technology process combining low power CMOS with fast switching bipolar technology. All inputs and outputs contain protection against ESD; all driver outputs feature high source and sink current capability. An epitaxial layer is used to guard against latch-up.

The ADM1485 features extremely fast switching speeds. Minimal driver propagation delays permit transmission at data rates up to 30 Mbits/s while low skew minimizes EMI interference.

The part is fully specified over the commercial and industrial temperature range and is available in an 8-pin DIL/ SOIC package.

ADM1485AQ	−40°C to +85°C	Q-8

*For outline information see Package Information section.

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the ADM1485 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

APPLICATIONS INFORMATION

Differential Data Transmission

Differential data transmission is used to reliably transmit data at high rates over long distances and through noisy environments. Differential transmission nullifies the effects of ground shifts and noise signals which appear as common-mode voltages on the line. There are two main standards approved by the Electronics Industries Association (EIA) which specify the electrical characteristics of transceivers used in differential data transmission.

The RS-422 standard specifies data rates up to 10 MBaud and line lengths up to 4000 ft. A single driver can drive a transmission line with up to 10 receivers.

In order to cater for true multipoint communications, the RS-485 standard was defined. This standard meets or exceeds all the requirements of RS-422 but also allows for up to 32 drivers and 32 receivers to be connected to a single bus. An extended common-mode range of −7 V to +12 V is defined. The most significant difference between RS-422 and RS-485 is the fact that the drivers may be disabled thereby allowing more than one (32 in fact) to be connected to a single line. Only one driver should be enabled at time, but the RS-485 standard contains additional specifications to guarantee device safety in the event of line contention.

Cable and Data Rate

The transmission line of choice for RS-485 communications is a twisted pair. Twisted pair cable tends to cancel common-mode noise and also causes cancellation of the magnetic fields generated by the current flowing through each wire, thereby, reducing the effective inductance of the pair.

The ADM1485 is designed for bidirectional data communications on multipoint transmission lines. A typical application showing a multipoint transmission network is illustrated in Figure 26. An RS-485 transmission line can have as many as 32 transceivers on the bus. Only one driver can transmit at a particular time but multiple receivers may be enabled simultaneously.

As with any transmission line, it is important that reflections are minimized. This may be achieved by terminating the extreme ends of the line using resistors equal to the characteristic impedance of the line. Stub lengths of the main line should also be kept as short as possible. A properly terminated transmission line appears purely resistive to the driver.

Thermal Shutdown

The ADM1485 contains thermal shutdown circuitry which protects the part from excessive power dissipation during fault conditions. Shorting the driver outputs to a low impedance source can result in high driver currents. The thermal sensing circuitry detects the increase in die temperature and disables the driver outputs. The thermal sensing circuitry is designed to disable the driver outputs when a die temperature of 150°C is reached. As the device cools, the drivers are re-enabled at 140°C.

Propagation Delay

The ADM1485 features very low propagation delay ensuring maximum baud rate operation. The driver is well balanced ensuring distortion free transmission.

Another important specification is a measure of the skew between the complementary outputs. Excessive skew impairs the noise immunity of the system and increases the amount of electromagnetic interference (EMI).

Receiver Open-Circuit Fail Safe

The receiver input includes a fail-safe feature which guarantees a logic high on the receiver when the inputs are open circuit or floating.

Table III. Comparison of RS-422 and RS-485 Interface Standards

Specification	RS-422	RS-485
Transmission Type	Differential	Differential
Maximum Cable Length	4000 ft.	4000 ft.
Minimum Driver Output Voltage	±2 V	±1.5 V
Driver Load Impedance	100 Ω	54 Ω
Receiver Input Resistance	4 kΩ min	12 kΩ min
Receiver Input Sensitivity	±200 mV	±200 mV
Receiver Input Voltage Range	−7 V to +7 V	−7 V to +12 V
No of Drivers/Receivers Per Line	1/10	32/32

ANALOG DEVICES

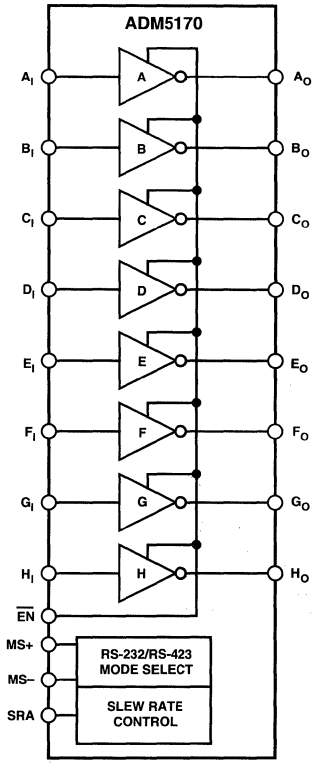
Octal, RS-232/RS-423 Line Driver

ADM5170

FEATURES
Eight Single Ended Line Drivers in One Package
Meets EIA Standard RS-232E, RS-423A and CCITT V.10/X.26
Resistor Programmable Slew Rate
Wide Supply Voltage Range
Low Power CMOS
3-State Outputs
TTL/CMOS Compatible Inputs
Output Short Circuit Protection
Available in 28-Pin DIP/PLCC
Low Power Replacement for UC5170C

APPLICATIONS
High Speed Communication
Computer I-O Ports Peripherals
High Speed Modems
Printers
Logic Level Translation

FUNCTIONAL BLOCK DIAGRAM



GENERAL DESCRIPTION

The ADM5170 is an octal line driver suitable for digital communication systems with data rates up to 116 kB/s. Input TTL or CMOS signal levels are inverted and translated into either EIA RS-232E or RS-423A signal levels depending on the status of the Mode Select inputs MS+ and MS–. With both Mode Select inputs at GND, RS-423 operation is selected while with MS+ connected to V_{DD} and MS– connected to V_{SS}, RS-232 operation is selected.

The output slew rates may be controlled using an external resistor connected between the SRA (Slew Rate Adjust) pin and GND. Resistor values between 2 kΩ and 10 kΩ may be selected giving a slew rate which can be adjusted from 10 V/μs to 2.2 V/μs. This adjustment of the slew rate allows tailoring of the output characteristics to suit the interface cable being used.

The outputs may be disabled using the $\overline{EN}$ (Enable Input). This feature permits sharing of a common output line.

The ADM5170 is fabricated on an advanced CMOS process featuring low power consumption. In the disabled state the power consumption reduces from 500 mW to 40 mW. The ADM5170 is available in both 28-pin DIP and 28-lead PLCC packages.

Truth Table

Inputs $\overline{EN}$	Data	Outputs EIA RS-232E[1]	RS-423A
0	0	(V_{DD} – 3 V)	5 V to 6 V
0	1	(V_{SS} – 3 V)	–5 V to –6 V
1	X	High Z	High Z

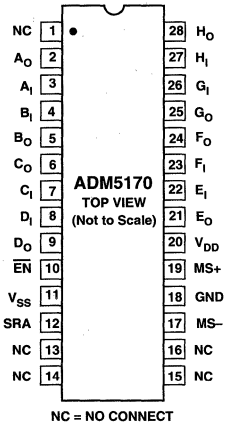
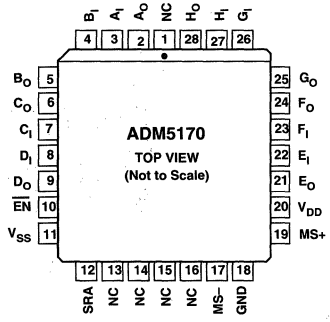
PIN CONFIGURATIONS

DIP



NC = NO CONNECT

PLCC



NC = NO CONNECT

PIN FUNCTION DESCRIPTION

Mnemonic	Function
V_{DD}	Power Supply Input, +10 V ± 10%.
V_{SS}	Power Supply Input, –10 V ± 10%.
GND	Ground Pin. Must be connected to 0 V.
$A_I \ldots H_I$	Digital Input to Drivers A to H.
$A_O \ldots H_O$	RS-232/RS-423 Output from Drivers A to H.
$\overline{EN}$	Enable Pin. When high, all outputs are 3-stated.
MS+, MS–	Mode Select Inputs. Used to control the output level swing. With MS+ & MS– connected to GND, RS-423A output levels are selected. With MS+ connected to V_{DD} and MS– connected to V_{SS}, RS-232 output levels are developed.
SRA	Slew Rate Adjust Input. An external resistor (2 kΩ to 10 kΩ) connected between this pin and GND is used to control the Output Slew Rate (10 V/µs to 2.2 V/µs).

Slew Rate Programming

The slew rate for the ADM5170 is controlled by a single resistor connected between the SRA pin and GND. The slew rate is approximately.

$$Slew\ Rate\ (V/\mu s) = 20/R_{SRA}\ (k\Omega)$$

Resistors between 2 kΩ and 10 kΩ may be used providing a slew rate which may be varied from 10 V/µs to 2.2 V/µs. Figure 5 in the Typical Performance Characteristics section shows how the slew rate varies with R_{SRA} while Figure 8 shows how the transition time (10% to 90%) varies with R_{SRA}. Waveshaping of the output allows the user to control the level of interference (near-end crosstalk) which may be coupled to adjacent circuits in an interconnection. The recommended output characteristics for cable length and data rate are given in the EIA RS-423A specifications.

Maximum Data Rate (kB/s) = 300/t (for rates from 1 kB/s to 100 kB/s).

$$Cable\ Length\ (feet) = 100\ X\ t\ (Max\ Length = 4000\ ft.)$$

where t is the transition time (in µs) for the output to swing from 10% to 90% of its steady state values. The absolute maximum data rate is 100 kB/s and the maximum cable length is limited to 4000 ft.

Output Mode Programming

The ADM5170 has two programmable output modes which provide different output voltage levels. The low output mode meets the specifications of EIA standards RS-423A while the high output mode meets the RS-232 specifications. The high output mode provides greater output swings and is suitable for driving lines where higher attenuation levels must be tolerated. This mode is selected by connecting the mode select pins to the supplies, MS+ to V_{DD} and MS– to V_{SS}. The low output mode is selected by connecting both mode select pins MS+ and MS– to GND. This mode provides a controlled output swing with lower output levels.

Inputs				Outputs
MS+	MS–	$\overline{EN}$	Data	Output
GND	GND	0	0	5 V to 6 V (RS-423)
GND	GND	0	1	–5 V to –6 V (RS-423)
V_{DD}	V_{SS}	0	0	(V_{DD} – 3 V) (RS-232)[1]
V_{DD}	V_{SS}	0	1	(V_{SS} + 3 V) (RS-232)[1]
X	X	1	X	High Z

[1]Minimum Output Level.

Typical Application Circuit

A typical application circuit using a single driver in the ADM5170 is shown in Figure 4. This circuit is suitable for either RS-232 or RS-423 communication. An ADM5180 octal receiver is used to translate the signal back to CMOS logic level at the receiving end.

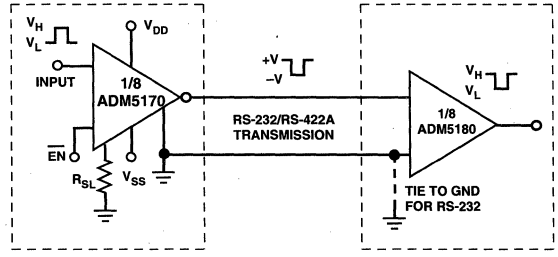


Figure 4. RS-232/RS-423A Typical Application Circuit

Octal, RS-232/RS-423 Line Receiver

ADM5180

FEATURES

Eight Differential Line Receivers in One Package
Meets EIA Standard EIA-232E, 423A, 422A and CCITT V.10, V.11, V.28
Single +5 V Supply
Differential Inputs Withstand ±25 V
Internal Hysteresis
Low Power CMOS –3.5 mA Supply Current
TTL/CMOS Compatible Outputs
Available in 28-Pin DIP and PLCC Packages
Low Power Replacement for UC5180C/NE5180

APPLICATIONS

High Speed Communication
Computer I-O Ports
Peripherals
High Speed Modems
Printers
Logic Level Translation

GENERAL DESCRIPTION

The ADM5180 is an octal differential line receiver suitable for a wide range of digital communication systems with data rates up to 200 kB/s. Input signals conforming to EIA Standards 232-E, 422A and CCITT V.10, V.11, V.28, X.26, and X.27 are accepted and translated into TTL /CMOS output signal levels.

The ADM5180 is a superior upgrade for the UC5180C and the NE5180. It is fabricated on an advanced BiCMOS process, allowing high speed bipolar circuitry to be combined with low power CMOS. This minimizes the power consumption to less than 25 mW.

A failsafe function ensures a known output state under a variety of input fault conditions as defined in RS-422A and RS-423A. The failsafe function is controlled by FS1 and FS2. Each controls four receivers. With FS = Low and a fault condition the output is forced low while if FS = High, the output is forced high.

The device is available in both 28-pin DIP and 28-lead PLCC packages.

FS1, FS2	A through D and FS2 controls receivers E through H. Failsafe Control Inputs. FS1 controls receivers A through D and FS2 control Receiver E through H.

APPLICATIONS INFORMATION

FAILSAFE OPERATION

The ADM5180 provides a failsafe operating mode to guard against input fault conditions as defined in RS-422A and RS-423A standards. The fault conditions are (1) Driver in power-off condition, (2) Receiver not interconnected with Driver, (3) Open-circuited interconnecting cable, and (4) Short-circuited interconnecting cable. If any of these four fault conditions occurs at the inputs of a receiver, then the output of that receiver is driven to a known logic level. The failsafe level is programmed using the failsafe (FS) input. There are two failsafe inputs, FS1 and FS2 which each control four receivers. FSI controls receivers A . . . D and FS2 controls receivers E . . . H. A connection to V_{DD} on the failsafe input sets the output high under fault conditions while a connection to GND sets the output low.

FS1, FS2	Output During Fault Condition
V_{DD}	High
GND	Low

Input Filtering

The ADM5180 contains internal low pass filtering for additional noise rejection. Frequencies above the passband will be rejected. For the specified input (5.5 MHz at ±500 mV) the input stage attenuates the signal such that the threshold levels are not reached and therefore no change of state occurs on the output. The filtering is a function of both amplitude and and frequency. As the signal amplitude decreases then the rejected frequency will decrease.

ANALOG DEVICES

Variable Resolution, Monolithic Resolver-to-Digital Converter

AD2S80A

FEATURES

Monolithic (BiMOS II) Tracking R/D Converter
40-Pin DIP Package
44-Pin LCC Package
10-, 12-, 14- and 16-Bit Resolution Set by User
Ratiometric Conversion
Low Power Consumption: 300 mW typ
Dynamic Performance Set by User
High Max Tracking Rate 1040 RPS (10 Bits)
Velocity Output
Industrial Temperature Range Versions
Military Temperature Range Versions
ESD Class 2 Protection (2,000 V min)
/883 B Parts Available

APPLICATIONS

DC Brushless and AC Motor Control
Process Control
Numerical Control of Machine Tools
Robotics
Axis Control
Military Servo Control

GENERAL DESCRIPTION

The AD2S80A is a monolithic 10-, 12-, 14- or 16-bit tracking resolver-to-digital converter contained in a 40-pin DIP or 44-pin LCC ceramic package. It is manufactured on a BiMOS II process that combines the advantages of CMOS logic and bipolar high accuracy linear circuits on the same chip.

The converter allows users *to select their own resolution and dynamic performance with external components*. This allows the users great flexibility in defining the converter that best suits their system requirements. The converter allows users to select the resolution to be 10, 12, 14 or 16 bits and to track resolver signals rotating at up to 1040 revs per second (62,400 rpm) when set to 10-bit resolution.

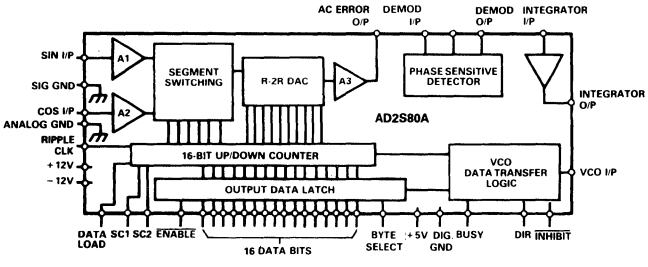
The AD2S80A converts resolver format input signals into a parallel natural binary digital word using a ratiometric tracking conversion method. This ensures high-noise immunity and tolerance of lead length when the converter is remote from the resolver.

The 10-, 12-, 14- or 16-bit output word is in a three-state digital logic available in 2 bytes on the 16 output data lines. BYTE SELECT, $\overline{\text{ENABLE}}$ and $\overline{\text{INHIBIT}}$ pins ensure easy data transfer to 8- and 16-bit data buses, and outputs are provided to allow for cycle or pitch counting in external counters.

An analog signal proportional to velocity is also available and can be used to replace a tachogenerator.

The AD2S80A operates over 50 Hz to 20,000 Hz reference frequency.

FUNCTIONAL BLOCK DIAGRAM



PRODUCT HIGHLIGHTS

Monolithic. A one chip solution reduces the package size required and increases the reliability.

Resolution Set by User. Two control pins are used to select the resolution of the AD2S80A to be 10, 12, 14 or 16 bits allowing the user to use the AD2S80A with the optimum resolution for each application.

Ratiometric Tracking Conversion. Conversion technique provides continuous output position data without conversion delay and is insensitive to absolute signal levels. It also provides good noise immunity and tolerance to harmonic distortion on the reference and input signals.

Dynamic Performance Set by the User. By selecting external resistor and capacitor values the user can determine bandwidth, maximum tracking rate and velocity scaling of the converter to match the system requirements. The external components required are all low cost preferred value resistors and capacitors, and the component values are easy to select using the simple instructions given.

Velocity Output. An analog signal proportional to velocity is available and is linear to typically one percent. This can be used in place of a velocity transducer in many applications to provide loop stabilization in servo controls and velocity feedback data.

Low Power Consumption. Typically only 300 mW.

Military Product. The AD2S80A is available processed in accordance with MIL-STD-883B, Class B.

MODELS AVAILABLE

Information on the models available is given in the section "Ordering Guide."

NOTES
[1]Refers to small signal bandwidth.
[2]Output offset dependent on value for R6.
[3]Refer to timing diagram.

Specifications subject to change without notice.

All min and max specifications are guaranteed. Specifications in **boldface** are tested on all production units at final electrical test.

ESD SENSITIVITY

The AD2S80A features an input protection circuit consisting of large "distributed" diodes and polysilicon series resistors to dissipate both high energy discharges (Human Body Model) and fast, low energy pulses (Charges Device Model).

The AD2S80A is ESD protection Class II (2000 V min). Proper ESD precautions are strongly recommended to avoid functional damage or performance degradation. For further information on ESD precautions, refer to Analog Devices *ESD Prevention Manual.*

GENERAL DESCRIPTION

The AD2S82A is a monolithic 10-, 12-, 14- or 16-bit tracking resolver-to-digital converter contained in a 44-pin J leaded PLCC package. Two extra functions are provided in the new surface mount package – COMPLEMENT and VCO output.

The AD2S81A is a monolithic 12-bit fixed resolution tracking resolver-to-digital converter packaged in a 28-pin DIP.

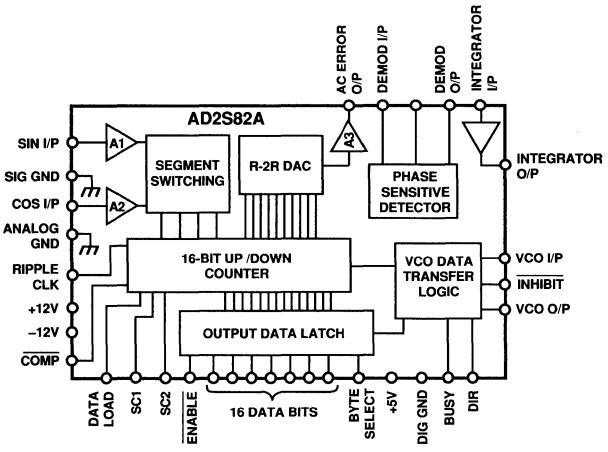
The converters allow users to *select their own dynamic performance with external components*. This allows the users great flexibility in defining the converter that best suits their system requirements. The AD2S82A allows users to select the resolution to be 10, 12, 14 or 16 bits and to track resolver signals rotating at up to 1040 revs per second (62,400 rpm) when set to 10-bit resolution.

The AD2S81A and AD2S82A convert resolver format input signals into a parallel natural binary digital word using a ratiometric tracking conversion method. This ensures high-noise immunity and tolerance of lead length when the converter is remote from the resolver.

The output word is in a three-state digital logic form available in 2 bytes on the 16 output data lines for the AD2S82A and on 8 output data lines for the AD2S81A. BYTE SELECT, $\overline{\text{ENABLE}}$ and $\overline{\text{INHIBIT}}$ pins ensure easy data transfer to 8- and 16-bit data buses, and outputs are provided to allow for cycle or pitch counting in external counters.

An analog signal proportional to velocity is also available and can be used to replace a tachogenerator.

AD2S82A FUNCTIONAL BLOCK DIAGRAM



PRODUCT HIGHLIGHTS

Monolithic. A one-chip solution reduces the package size required and increases the reliability.

Resolution Set by User. Two control pins are used to select the resolution of the AD2S82A to be 10, 12, 14 or 16 bits allowing the user to use the AD2S82A with the optimum resolution for each application.

Ratiometric Tracking Conversion. Conversion technique provides continuous output position data without conversion delay and is insensitive to absolute signal levels. It also provides good noise immunity and tolerance to harmonic distortion on the reference and input signals.

Dynamic Performance Set by the User. By selecting external resistor and capacitor values the user can determine bandwidth, maximum tracking rate and velocity scaling of the converter to match the system requirements. The external components required are all low cost, preferred value resistors and capacitors, and the component values are easy to select using the simple instructions given.

Velocity Output. An analog signal proportional to velocity is available and is linear to typically one percent. This can be used in place of a velocity transducer in many applications to provide loop stabilization in servo controls and velocity feedback data.

Low Power Consumption. Typically only 300 mW.

MODELS AVAILABLE

Information on the models available is given in the section "Ordering Information."

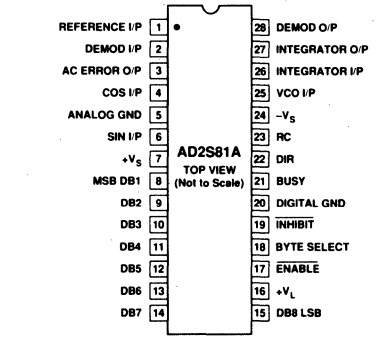
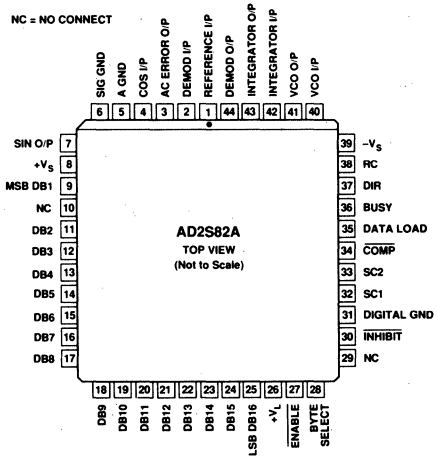
CAUTION:

1. Absolute Maximum Ratings are those values beyond which damage to the device may occur.
2. Correct polarity voltages must be maintained on the $+V_S$ and $-V_S$ pins.

PIN CONFIGURATIONS





CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 volts, which readily accumulate on the human body and on test equipment, can discharge without detection. Although devices feature proprietary ESD protection circuitry, permanent damage may still occur on these devices if they are subjected to high energy electrostatic discharges. Therefore, proper precautions are recommended to avoid any performance degradation or loss of functionality.

Variable Resolution, Monolithic Resolver-to-Digital Converter

AD2S83

FEATURES
Monolithic Tracking R/D Converter
High Accuracy Velocity Output
High Max Tracking Rate 1040 RPS (10 Bits)
44-Pin PLCC Package
10-, 12-, 14- or 16-Bit Resolution Set by User
Ratiometric Conversion
Stabilized Velocity Reference
Dynamic Performance Set by User
Industrial Temperature Range Versions

APPLICATIONS
DC and AC Servo Motor Control
Process Control
Numerical Control of Machine Tools
Robotics
Axis Control

GENERAL DESCRIPTION

The AD2S83 is a monolithic 10-, 12-, 14- or 16-bit tracking resolver-to-digital converter contained in a 44-pin PLCC package. It is manufactured on Analog Devices' BiMOS II process that combines the advantages of CMOS logic and bipolar high accuracy linear circuits on the same chip.

The converter allows users *to select their own resolution and dynamic performance with external components*. This allows the users great flexibility in defining the converter that best suits their system requirements. The converter allows users to select the resolution to be 10, 12, 14 or 16 bits and to track resolver signals rotating at up to 1040 revs per second (62,400 rpm) when set to 10-bit resolution.

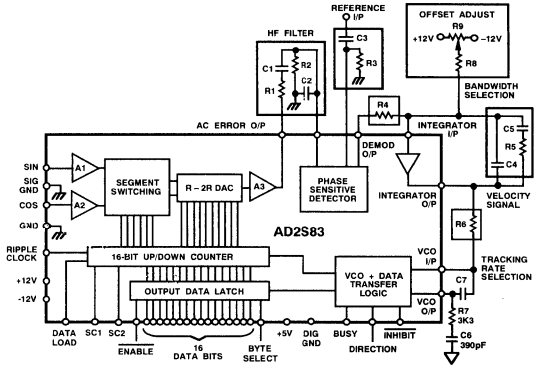
The AD2S83 converts resolver format input signals into a parallel natural binary digital word using a ratiometric tracking conversion method. This ensures high noise immunity and tolerance of long leads allowing the converter to be located remote from the resolver.

The position output from the converter is presented via 3-state output pins which can be configured for operations with 8- or 16-bit bus. BYTE SELECT, $\overline{\text{ENABLE}}$ and $\overline{\text{INHIBIT}}$ pins ensure easy data transfer to 8- and 16-bit data bus, and outputs are provided to allow for cycle or pitch counting in external counters.

A precise analog signal proportional to velocity is also available and will replace a tachogenerator.

The AD2S83 operates over reference frequencies in the range 0 Hz to 20,000 Hz.

FUNCTIONAL BLOCK DIAGRAM



PRODUCT HIGHLIGHTS

High Accuracy Velocity Output. A precision analog velocity signal with a typical linearity of ±0.1% and reversion error less than ±0.3% is generated by the AD2S83. The provision of this signal removes the need for mechanical tachogenerators used in servo systems to provide loop stabilization and speed control.

Monolithic. A one-chip solution reduces the package size and increases the reliability.

Resolution Set by User. Two control pins are used to select the resolution of the AD2S83 to be 10, 12, 14 or 16 bits allowing the user to use the AD2S83 with the optimum resolution for each application.

Ratiometric Tracking Conversion. This technique provides continuous output position data without conversion delay and is insensitive to absolute signal levels. It also provides good noise immunity and tolerance to harmonic distortion on the reference and input signals.

Dynamic Performance Set by the User. By selecting external resistor and capacitor values the user can determine bandwidth, maximum tracking rate and velocity scaling of the converter to match the system requirements. The external components required are all low cost, preferred value resistors and capacitors, and the component values are easy to select using the free component selection software design aid.

MODELS AVAILABLE

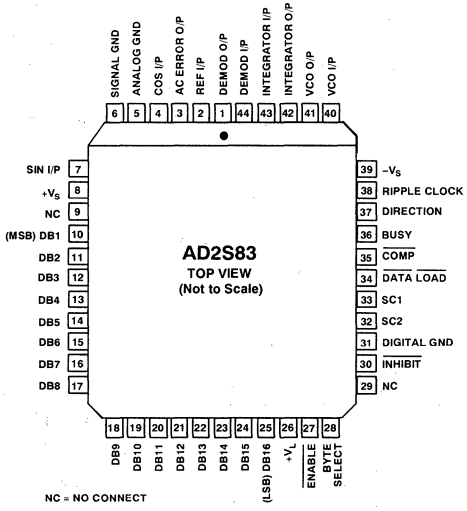
PIN CONFIGURATION



PIN DESIGNATIONS

Pin Nos.	Mnemonic	Description
1	DEMOD O/P	Demodulator Output
2	REFERENCE I/P	Reference Signal Input
3	AC ERROR O/P	Ratio Multiplier Output
4	COS	Cosine Input
5	ANALOG GND	Power Ground
6	SIGNAL GND	Resolver Signal Ground
7	SIN	Sine Input
8	$+V_S$	Positive Power Supply
10–25	DB 1–DB 16	Parallel Output Data
26	$+V_L$	Logic Power Supply
27	$\overline{\text{ENABLE}}$	Logic HI–Output Data Pins in High Impedance State Logic LO–Presents Active Data to the Output Pins
28	BYTE SELECT	Logic HI–Most Significant Byte to DB1–DB8 Logic LO–Least Significant Byte to DB1–DB8
30	$\overline{\text{INHIBIT}}$	Logic LO Inhibits Data Transfer to Output Latches
31	DIGITAL GND	Digital Ground
32, 33	SC2–SC1	Select Converter Resolution
34	$\overline{\text{DATA LOAD}}$	Logic LO DB1–DB16 Inputs Logic HI DB1–DB16 Outputs
35	$\overline{\text{COMPLEMENT}}$	Active Logic LO
36	BUSY	Converter Busy, Data not Valid While Busy HI
37	DIRECTION	Logic State Defines Direction of Input Signal Rotation
38	RIPPLE CLOCK	Positive Pulse When Converter Output Changes from 1s to All 0s or Vice Versa
39	$-V_S$	Negative Power Supply
40	VCO I/P	VCO Input
41	VCO O/P	VCO Output
42	INTEGRATOR O/P	Integrator Output
43	INTEGRATOR I/P	Integrator Input
44	DEMOD I/P	Demodulator Input

ESD SENSITIVITY

The AD2S83 features an input protection circuit consisting of large "distributed" diodes and polysilicon series resistors to dissipate both high energy discharges (Human Body Model) and fast, low energy pulses (Charges Device Model).

Proper ESD precautions are strongly recommended to avoid functional damage or performance degradation. For further information on ESD precautions, refer to Analog Devices *ESD Prevention Manual.*

CONNECTING THE CONVERTER

The power supply voltages connected to $+V_S$ and $-V_S$ pins should be +12 V dc and −12 V dc and must not be reversed. The voltage applied to V_L can be +5 V dc to $+V_S$.

It is recommended that decoupling capacitors are connected in parallel between the power lines $+V_S$, $-V_S$ and ANALOG GROUND adjacent to the converter. Recommended values are 100 nF (ceramic) and 10 μF (tantalum). Also capacitors of 100 nF and 10 μF should be connected between $+V_L$ and DIGITAL GROUND adjacent to the converter.

When more than one converter is used on a card, separate decoupling capacitors should be used for each converter.

The resolver signal connections should be made to the SIN and COS inputs, REFERENCE INPUT and SIGNAL GROUND as shown in Figure 10 and described in section "CONNECTING THE RESOLVER."

The two signal ground wires from the resolver should be joined at the SIGNAL GROUND pin of the converter to minimize the coupling between the sine and cosine signals. For this reason it is also recommended that the resolver is connected using individually screened twisted pair cables with the sine, cosine and reference signals twisted separately.

SIGNAL GROUND and ANALOG GROUND are connected internally. ANALOG GROUND and DIGITAL GROUND must be connected externally and as close to the converter as possible.

The external components required should be connected as shown in Figure 1.

CONVERTER RESOLUTION

Two major areas of the AD2S83 specification can be selected by the user to optimize the total system performance. The resolution of the digital output is set by the logic state of the inputs SC1 and SC2 to be 10, 12, 14 or 16 bits; and the dynamic characteristics of bandwidth and tracking rate are selected by the choice of external components.

The choice of the resolution will affect the values of R4 and R6 which scale the inputs to the integrator and the VCO respectively (see section COMPONENT SELECTION). If the resolution is changed, then new values of R4 and R6 must be switched into the circuit.

Note: When changing resolution under dynamic conditions, do so when BUSY is low, i.e., when data is not changing.

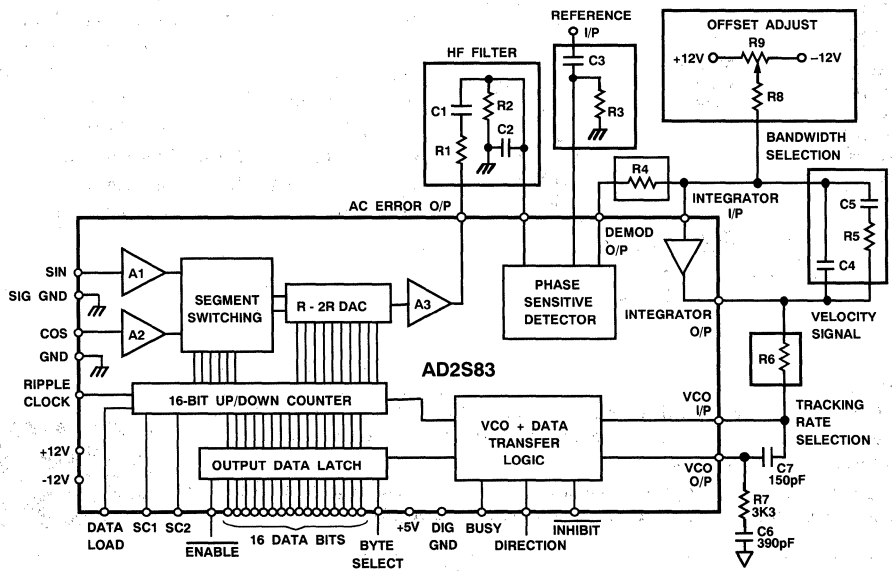

Figure 1. Connection Diagram

CONVERTER OPERATION

When connected in a circuit such as shown in Figure 10, the AD2S83 operates as a tracking resolver-to-digital converter. The output will automatically follow the input for speeds up to the selected maximum tracking rate. No convert command is necessary as the conversion is automatically initiated by each LSB increment, or decrement, of the input. Each LSB change of the converter initiates a BUSY pulse.

The AD2S83 is remarkably tolerant of input amplitude and frequency variation because the conversion depends only on the ratio of the input signals. Consequently there is no need for accurate, stable oscillator to produce the reference signal. The inclusion of the phase sensitive detector in the conversion loop ensures high immunity to signals that are not phase or frequency coherent or are in quadrature with the reference signal.

SIGNAL CONDITIONING

The amplitude of the SINE and COSINE signal inputs should be maintained within 10% of the nominal values if full performance is required from the velocity signal.

The digital position output is relatively insensitive to amplitude variation. Increasing the input signal levels by more than 10% will result in a loss in accuracy due to internal overload. Reducing levels will result in a steady decline in accuracy. With the signal levels at 50% of the correct value, the angular error will increase to an amount equivalent to 1.3 LSB. At this level the repeatability will also degrade to 2 LSB and the dynamic response will also change, since the dynamic characteristics are proportional to the signal level.

The AD2S83 will not be damaged if the signal inputs are applied to the converter without the power supplies and/or the reference.

REFERENCE INPUT

The amplitude of the reference signal applied to the converter's input is not critical, but care should be taken to ensure it is kept within the recommended operating limits.

The AD2S83 will not be damaged if the reference is supplied to the converter without the power supplies and/or the signal inputs.

HARMONIC DISTORTION

The amount of harmonic distortion allowable on the signal and reference lines is 10%.

Square waveforms can be used but the input levels should be adjusted so that the average value is 1.9 V rms. (For example, a square wave should be 1.9 V peak.) Triangular and sawtooth waveforms should have a amplitude of 2 V rms.

Note: The figure specified of 10% harmonic distortion is for calibration convenience only.

POSITION OUTPUT

The resolver shaft position is represented at the converter output by a natural binary parallel digital word. As the digital position output of the converter passes through the major carries, i.e., all "1s" to all "0s" or the inverse, a RIPPLE CLOCK (RC) logic output is initiated indicating that a revolution or a pitch of the input has been completed.

The direction of input rotation is indicated by the DIRECTION (DIR) logic output. This direction data is always valid in advance of a RIPPLE CLOCK pulse and, as it is internally latched, only changing state (1 LSB min change in input) with a corresponding change in direction.

Both the RIPPLE CLOCK pulse and the DIRECTION data are unaffected by the application of the $\overline{\text{INHIBIT}}$. The static positional accuracy quoted is the worst case error that can occur over the full operating temperature excluding the effects of offset signals at the INTEGRATOR INPUT (which can be trimmed out – see Figure 1), and with the following conditions: input signal amplitudes are within 10% of the nominal; phase shift between signal and reference is less than 10 degrees.

These operating conditions are selected primarily to establish a repeatable acceptance test procedure which can be traced to national standards. In practice, the AD2S83 can be used well outside these operating conditions providing the above points are observed.

VELOCITY SIGNAL

The tracking converter technique generates an internal signal at the output of the integrator (INTEGRATOR OUTPUT) that is proportional to the rate of change of the input angle. This is a dc analog output referred to as the VELOCITY signal.

It is recommended that the velocity output be buffered.

The sense is positive for an increasing angular input and negative for decreasing angular input. The full-scale velocity output is ±8 V dc. The output velocity scaling and tracking rate are a function of the resolution of the converter; this is summarized below.

Res	Max Tracking Rate (rps)	Nominal Scaling (rps/V dc)
10	1040	130
12	260	32.5
14	65	8.125
16	16.25	2.03

(Velocity O/P = ±8 V dc nominal)

The output velocity can be suitably scaled and used to replace a conventional DC tachogenerator. For more detailed information see "AD2S83 as a Silicon Tachogenerator" section.

DC ERROR SIGNAL

The signal at the output of the phase sensitive detector (DEMODULATOR OUTPUT) is the signal to be nulled by the tracking loop and is, therefore, proportional to the error between the input angle and the output digital angle. As the converter is a Type 2 servo loop, the demodulator output signal will increase if the output fails to track the input for any reason. This is an indication that the input has exceeded the maximum tracking rate of the converter or, due to some internal or external malfunction, the converter is unable to reach a null. By connecting two external comparators, this voltage can be used as a "built-in-test."

COMPONENT SELECTION

The following instructions describe how to select the external components for the converter in order to achieve the required bandwidth and tracking rate. In all cases the nearest "preferred value" component should be used, and a 5% tolerance will not degrade the overall performance of the converter. Care should be taken that the resistors and capacitors will function over the required operating temperature range. The components should be connected as shown in Figure 1.

Free PC compatible software is available to help users select the optimum component values for the AD2S83, and display the transfer gain, phase and small step response.

For more detailed information and explanation, see section "CIRCUIT FUNCTIONS AND DYNAMIC PERFORMANCE."

1. HF Filter (R1, R2, C1, C2)
   The function of the HF filter is to remove any dc offset and to reduce the amount of noise present on the signal inputs to the AD2S83, reaching the Phase Sensitive Detector and affecting the outputs. R1 and C2 may be omitted – in which case R2 = R3 and C1 = C3, calculated below – but their use is particularly recommended if noise from switch mode power supplies and brushless motor drive is present.

   Values should be chosen so that

   $$15\ k\Omega \leq R1 = R2 \leq 56\ k\Omega$$

   $$C1 = C2 = \frac{1}{2\ \pi\ R1\ f_{REF}}$$

   and f_{REF} = Reference frequency (Hz)

   This filter gives an attenuation of 3 times at the input to the phase sensitive detector.

2. Gain Scaling Resistor (R4) (See Phase Sensitive Demodulator Section)
   If R1, C2 are fitted then:

   $$R4 = \frac{E_{DC}}{100 \times 10^{-9}} \times \frac{1}{3}\ \Omega$$

   where 100×10^{-9} = current/LSB
   If R1, C2 are not fitted then:

   $$R4 = \frac{E_{DC}}{100 \times 10^{-9}}\ \Omega$$

   where E_{DC} = 160×10^{-3} for 10 bits resolution
   = 40×10^{-3} for 12 bits
   = 10×10^{-3} for 14 bits
   = 2.5×10^{-3} for 16 bits
   = Scaling of the DC ERROR in volts/LSB

3. AC Coupling of Reference Input (R3, C3)
   Select R3 and C3 so that there is no significant phase shift at the reference frequency. That is,

   $$R3 = 100\ k\Omega$$

   $$C3 > \frac{1}{R3 \times f_{REF}}\ F$$

   with R3 in Ω.

4. Maximum Tracking Rate (R6)
   The VCO input resistor R6 sets the maximum tracking rate of the converter and hence the velocity scaling as at the max tracking rate, the velocity output will be 8 V.

   Decide on your maximum tracking rate, "T," in revolutions per second. When setting the value for R6, it should be remembered that the linearity of the velocity output is specified across 0 kHz–500 kHz and 500 kHz–1000 kHz. The following conversion can be used to determine the corresponding rps:

   $$rps = \frac{VCO\ Rate\ (Hz)}{2^N}$$

   Note that "T" must not exceed the maximum tracking rate or 1/16 of the reference frequency.

   $$R6 = \frac{6.81 \times 10^{10}}{T \times n}\ \Omega$$

   where n = bits per revolution
   = 1,024 for 10 bits resolution
   = 4,096 for 12 bits
   = 16,384 for 14 bits
   = 65,536 for 16 bits

5. Closed-Loop Bandwidth Selection (C4, C5, R5)
   a. Choose the closed-loop bandwidth (f_{BW}) required ensuring that the ratio of reference frequency to bandwidth does not exceed the following guidelines:

Resolution	Ratio of Reference Frequency/Bandwidth
10	2.5 : 1
12	4 : 1
14	6 : 1
16	7.5 : 1

   Typical values may be 100 Hz for a 400 Hz reference frequency and 500 Hz to 1000 Hz for a 5 kHz reference frequency.

   b. Select C4 so that

   $$C4 = \frac{21}{R6 \times f_{BW}^2}\ F$$

   with R6 in Ω and f_{BW} in Hz selected above.

   c. C5 is given by

   $$C5 = 5 \times C4$$

   d. R5 is given by

   $$R5 = \frac{4}{2 \times \pi \times f_{BW} \times C5}\ \Omega$$

6. VCO Phase Compensation
   The following values of C6 and R7 should be connected as close as possible to the VCO output, Pin 41.

   $$C6 = 390\ pF,\ R7 = 3.3\ k\Omega$$

7. VCO Optimization
   To optimize the performance of the VCO a capacitor, C7, should be placed across the VCO input and output, Pins 40 and 41.

   $$C7 = 150\ pF$$

8. Offset Adjust
   Offsets and bias currents at the integrator input can cause an additional positional offset at the output of the converter of 1 arc minute typical, 5.3 arc minutes maximum. If this can be tolerated, then R8 and R9 can be omitted from the circuit.

   If fitted, the following values of R8 and R9 should be used:

   $$R8 = 4.7\ M\Omega,\ R9 = 1\ M\Omega\ potentiometer$$

To adjust the zero offset, ensure the resolver is disconnected and all the external components are fitted. Connect the COS pin to the REFERENCE INPUT and the SIN pin to the SIGNAL GROUND and with the power and reference applied, adjust the potentiometer to give all "0s" on the digital output bits.

The potentiometer may be replaced with select on test resistors if preferred.

DATA TRANSFER

To transfer data the $\overline{\text{INHIBIT}}$ input should be used. The data will be valid 490 ns after the application of a logic "LO" to the $\overline{\text{INHIBIT}}$. This is regardless of the time when the $\overline{\text{INHIBIT}}$ is applied and allows time for an active BUSY to clear. By using the $\overline{\text{ENABLE}}$ input the two bytes of data can be transferred after which the $\overline{\text{INHIBIT}}$ should be returned to a logic "HI" state to enable the output latches to be updated.

BUSY Output

The validity of the output data is indicated by the state of the BUSY output. When the input to the converter is changing, the signal appearing on the BUSY output is a series of pulses at TTL levels. A BUSY pulse is initiated each time the input moves by the analog equivalent of one LSB and the internal counter is incremented or decremented.

$\overline{\text{INHIBIT}}$ Input

The $\overline{\text{INHIBIT}}$ logic input only inhibits the data transfer from the up-down counter to the output latches and, therefore, does not interrupt the operation of the tracking loop. Releasing the $\overline{\text{INHIBIT}}$ automatically generates a BUSY pulse to refresh the output data.

$\overline{\text{ENABLE}}$ Input

The $\overline{\text{ENABLE}}$ input determines the state of the output data. A logic "HI" maintains the output data pins in the high impedance condition, and the application of a logic "LO" presents the data in the latches at the output pins. The operation of the $\overline{\text{ENABLE}}$ has no effect on the conversion process.

BYTE SELECT Input

The BYTE SELECT input selects the byte of the position data to be presented at the data output pins DB1 to DB8. The least significant byte will be presented on data output pins DB9 to DB16 (with the $\overline{\text{ENABLE}}$ input taken to a logic "LO") regardless of the state of the BYTE SELECT pin. Note that when the AD2S83 is used with a resolution less than 16 bits the unused data lines are pulled to a logic "LO." A logic "HI" on the BYTE SELECT input will present the eight most significant data bits on data output pins DB1 through DB8. A logic "LO" will present the least significant byte on data outputs 1 to 8, i.e., data outputs 1 to 8 will duplicate data outputs 9 to 16.

The operation of the BYTE SELECT has no effect on the conversion process of the converter.

RIPPLE CLOCK

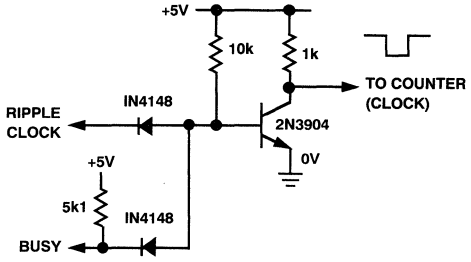
As the output of the converter passes through the major carry, i.e., all "1s" to all "0s" or the converse, a positive going edge on the RIPPLE CLOCK (RC) output is initiated indicating that a revolution, or a pitch, of the input has been completed.

The minimum pulse width of the ripple clock is 300 ns. RIPPLE CLOCK is normally set high before a BUSY pulse and resets before the next positive going edge of the next busy pulse.

The only exception to this is when DIR changes while the RIPPLE CLOCK is high. Resetting of the RIPPLE clock will only occur if the DIR remains stable for two consecutive positive BUSY pulse edges.

If the AD2S83 is being used in a pitch and revolution counting application, the ripple and busy will need to be gated to prevent false decrement or increment (see Figure 2).

RIPPLE CLOCK is unaffected by $\overline{\text{INHIBIT}}$.



NOTE: DO NOT USE ABOVE CCT WHEN $\overline{\text{INHIBIT}}$ IS LOW.

*ns

DIRECTION Output

The DIRECTION (DIR) output indicates the direction of the input rotation. Any change in the state of DIR precedes the corresponding BUSY, DATA and RIPPLE CLOCK updates. DIR can be considered as an asynchronous output and can make multiple changes in state between two consecutive LSB update cycles. This occurs when the direction of rotation of the input changes but the magnitude of the rotation is less than 1 LSB.

$\overline{\text{COMPLEMENT}}$

The $\overline{\text{COMPLEMENT}}$ input is an active low input and is internally pulled to $+V_S$ via 100 kΩ.

Strobing $\overline{\text{DATA LOAD}}$ and $\overline{\text{COMPLEMENT}}$ pins to logic LO will set the logic HI bits of the AD2S83 counter to a LO state. Those bits of the applied data which are logic LO will not change the corresponding bits in the AD2S83 counter.

For Example:

Initial Counter State	1 0 1 0 1
Applied Data Word	1 1 0 0 0
Counter State after $\overline{\text{DATA LOAD}}$	1 1 0 0 0
Initial Counter State	1 0 1 0 1
Applied Data Word	1 1 0 0 0
Counter State after $\overline{\text{DATA LOAD}}$ and Complement	0 0 1 0 1

In order to read the counter following a $\overline{\text{DATA LOAD}}$, the procedure below should be followed:

1. Place Outputs in high impedance state ($\overline{\text{ENABLE}}$ = HI).
2. Present data to pins.
3. Pull $\overline{\text{DATA LOAD}}$ and $\overline{\text{COMPLEMENT}}$ pins to ground.
4. Wait 100 ns.
5. Remove data from pins.
6. Remove outputs from high impedance state ($\overline{\text{ENABLE}}$ = LO).
7. Read outputs.

VELOCITY ERRORS

Some "ripple" or noise will always be present in the velocity signal. Velocity signal ripple is caused by, or related to, the following parameters. The resulting effects are generally additive. This means diagnosis needs to be an iterative process in order to define the source of the error.

1.0 Reference Frequency
A ripple content at the reference frequency is superimposed on the velocity signal output. The amplitude depends on the loop bandwidth. This error is a function of a dc offset at the input to Phase Sensitive Demodulator (PSD).

2.0 Resolver Inaccuracies
Impedance mismatch occur in the sine and cosine windings of the resolver. These give rise to differential phase shift between the sine and cosine inputs to the RDC and variations in the resolver output amplitudes.

2.1 Sine and Cosine Amplitude Mismatch
This is normally identified by the presence of asymmetrical ripple voltages.

2.2 Differential Phase Shift between the Sine and Cosine Inputs
The frequency of this ripple is usually twice the input velocity, and the amplitude is proportional to the magnitude of the velocity signal. The phase shift is normally induced through the connections from the resolver to the converter. Maintaining equal lengths of screened twisted pair cable from the resolver to the AD2S83 will reduce the effects of resistive imbalance, and therefore, reduce differential phase shift.

3.0 LSB Update Ripple
LSB update noise occurs as the resolver rotates and the digital outputs of the RDC are updated. For a correctly scaled loop, this ripple component has a magnitude of approximately 2 mV peak at 16-bit resolution.

3.1 Ripple due to the LSB rate given by:
LSB rate = N × Reference Frequency
The PSD generates sums and differences of all its component input frequencies, so when the LSB update rate is an multiple of the reference frequency, a beat frequency is generated. The magnitude of this ripple is a function of the LSB weighting, i.e., ripple is less at 16 bits.

4.0 Torque Ripple
Torque ripple is a phenomenon associated with motors. An ac motor naturally exhibits a sinusoidal back emf. In an ideal system the current fed to the motor should, in order to cancel, also be sinusoidal. In practice the current is often trapezoidal. Consequently, the output torque from the motor will not be smooth and torque ripple is created. If the loading on a motor is constant, the velocity of the motor shaft will vary as a result of the cyclic variation of motor torque. The variation in velocity then appears on the velocity output as ripple. This is not an error but a true velocity variation in the system.

Offset Errors

The limiting factor in the measuring of low or "creep" speeds is the level of dc offset present at zero velocity. The zero velocity dc offset at the output of the AD2S83 is a function of the input bias current to the VCO and the value for the input resistor R6. See "Circuit Functions and Dynamic Performance VCO."

The offset can be minimized by reducing the maximum tracking rate so reducing the value for R6. Offset is a function of tracking rate and therefore resolution; the dc offset is lowest at 16 bits. To increase the dynamic range of the velocity dynamic resolution switching can be employed. (Contact MCG Applications for more information.)

CONNECTING THE RESOLVER

The recommended connection circuit is shown in Figure 10.

In cases where the reference phase relative to the input signals from the resolver requires adjustment, this can be easily achieved by varying the value of the resistor R2 of the HF filter (see Figure 1).

Assume that R1 = R2 = R and C1 = C2 = C

and Reference Frequency = $\frac{1}{2\pi RC}$.

By altering the value of R2, the phase of the reference relative to the input signals will change in an approximately linear manner for phase shifts of up to 10 degrees.

Increasing R2 by 10% introduces a phase lag of 2 degrees. Decreasing R2 by 10% introduces a phase lead of 2 degrees.

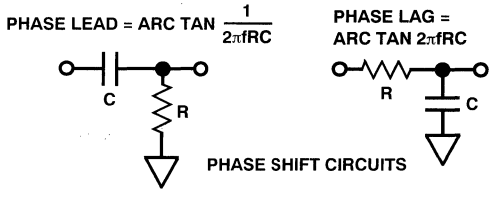

Figure 9. Phase Shift Circuits

16

TYPICAL CIRCUIT CONFIGURATION

Figure 10 shows a typical circuit configuration for the AD2S83 with 12-bit resolution. Values of the external components have been chosen for a reference frequency of 5 kHz and a maximum tracking rate of 260 rps with a bandwidth of 520 Hz. Placing the values for R4, R6, C4 and C5 in the equation for K_A gives a value of 2.7×10^6. The resistors are 0.125 W, 5% tolerance preferred values. The capacitors are 100 V ceramic, 10% tolerance components.

For signal and reference voltages greater than 2 V rms a simple voltage divider circuit of resistors can be used to generate the correct signal level at the converter. Care should be taken to ensure that the ratios of the resistors between the sine signal line and ground and the cosine signal line and ground are the same. Any difference will result in an additional position error.

Low Cost, Complete 12-Bit Resolver-to-Digital Converter

AD2S90

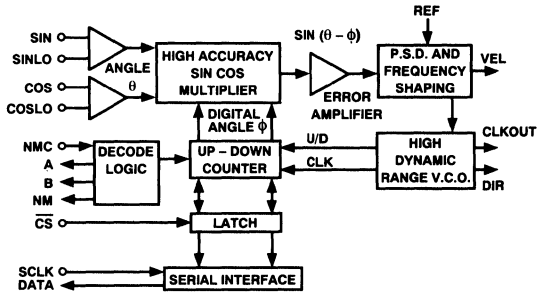
FEATURES

Complete Monolithic Resolver-to-Digital Converter
Incremental Encoder Emulation (1024-Line)
Absolute Serial Data (12-Bit)
Differential Inputs
12-Bit Resolution
Industrial Temperature Range
20-Pin PLCC
Low Power (50 mW)

APPLICATIONS

Industrial Motor Control
Servo Motor Control
Industrial Gauging
Encoder Emulation
Automotive Motion Sensing and Control
Factory Automation
Limit Switching

FUNCTIONAL BLOCK DIAGRAM



GENERAL DESCRIPTION

The AD2S90 is a complete 12-bit resolution tracking resolver-to-digital converter. No external components are required to operate the device.

The converter accepts 2 V rms ± 10% input signals in the range 3–20 kHz on the SIN, COS and REF inputs. A Type II servo loop is employed to track the inputs and convert the input SIN and COS information into a digital representation of the input angle. The bandwidth of the converter is set internally at 1 kHz. The maximum tracking rate is 375 rps at 12-bit resolution.

Angular position output information is available in two forms, absolute serial binary and incremental A quad B.

The absolute serial binary output is 12-bit (1 in 4096). The data output pin is high impedance when Chip Select $\overline{CS}$ is logic HI. This allows the connection of multiple converters onto a common bus. Absolute angular information in serial pure binary form is accessed by $\overline{CS}$ followed by the application of an external clock (SCLK) with a maximum rate of 2 MHz.

The encoder emulation outputs A, B and NM continuously produce signals equivalent to a 1024 line encoder. When decoded this corresponds to 12-bits resolution. Three common north marker pulse widths are selected via a single pin (NMC).

An analog velocity output signal provides a representation of velocity from a rotating resolver shaft travelling in either a clockwise or counterclockwise direction.

The AD2S90 operates on a ±5 V dc ± 5% power supplies and is fabricated on Analog Devices' Linear Compatible CMOS process (LC²MOS). LC²MOS is a mixed technology process that combines precision bipolar circuits with low power CMOS logic circuits.

PRODUCT HIGHLIGHTS

Complete Resolver–Digital Interface. The AD2S90 provides the complete solution for digitizing resolver signals (12-bit resolution) without the need for external components.

Dual Format Position Data. Incremental encoder emulation in standard A QUAD B format with selectable North Marker width. Absolute serial 12-bit angular binary position data accessed via simple 3-wire interface.

Single High Accuracy Grade in Low Cost Package. ±10.6 arc minutes of angular accuracy available in a 20-pin PLCC.

Low Power. Typically 50 mW power consumption.

NOTES
[1]Timing data are not 100% production tested. Sample tested at +25°C only to ensure conformance to data sheet limits. Logic output timing tests carried out using 10 pF, 100 kΩ load.
[2]Capacitance of data pin in high impedance state = 15 pF.

RECOMMENDED OPERATING CONDITIONS

Power Supply Voltage (V_{DD}–V_{SS}) . . . . . ±5 V dc ± 5%
Analog Input Voltage (SIN, COS & REF) . . . 2 V rms ± 10%
Signal and Reference Harmonic Distortion 10%
Phase Shift between Signal and Reference . . . . . ±10°
Ambient Operating Temperature Range
Industrial (AP) . . . . . −40°C to +85°C

ABSOLUTE MAXIMUM RATINGS*

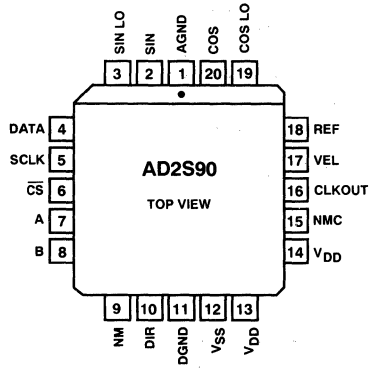
V_{DD} to AGND . . . . . −0.3 V dc to +7.0 V dc
V_{SS} to AGND . . . . . +0.3 V dc to −7.0 V dc
AGND to DGND . . . . . −0.3 V dc to V_{DD} + 0.3 V dc
Analog Inputs to AGND
REF . . . . . V_{SS} − 0.3 V dc to V_{DD} + 0.3 V dc
SIN, SIN LO . . . . . V_{SS} − 0.3 V dc to V_{DD} + 0.3 V dc
COS, COS LO . . . . . V_{SS} − 0.3 V dc to V_{DD} + 0.3 V dc
Analog Output to AGND
VEL . . . . . V_{SS} to V_{DD}
Digital Inputs to DGND, CSB,
SCLK, RES . . . . . −0.3 V dc to V_{DD} + 0.3 V dc
Digital Outputs to DGND, NM, A, B,
DIR, CLKOUT DATA . . . . −0.3 V dc to V_{DD} + 0.3 V dc
Operating Temperature Range
Industrial (AP) . . . . . −40°C to +85°C
Storage Temperature Range . . . . . −65°C to +150°C
Lead Temperature (Soldering 10 secs) . . . . . 300°C
Power Dissipation to +75°C . . . . . 300 mW
Derates above +75°C by . . . . . 10 mW/°C

*Stresses above those listed in "Absolute Maximum Ratings" may cause permanent damage to the device. This is a stress rating only and functional operation of the device at these or any other conditions above those indicated in the operational section is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.

ORDERING INFORMATION

Model	Temperature Range	Accuracy	Package Option*
AD2S90AP	−40°C to +85°C	8 arc min	P-20A

*P = Plastic Leaded Chip Carrier. For outline information see Package Information section.



PIN DESCRIPTIONS

Pin No.	Mnemonic	Function
1	AGND	Analog ground, reference ground.
2	SIN	SIN channel noninverting input connect to resolver SIN HI output. SIN to SIN LO = 2 V rms ± 10%.
3	SIN LO	SIN channel inverting input connect to resolver SIN LO.
4	DATA	Serial interface data output. High impedance with $\overline{CS}$ = HI. Enabled by $\overline{CS}$ = 0.
5	SCLK	Serial interface clock. Data is clocked out on "first" negative edge of SCLK after a LO transition on $\overline{CS}$. 12 SCLK pulses to clock data out.
6	$\overline{CS}$	Chip select. Active LO. Logic LO transition enables DATA output.
7	A	Encoder A output. A leads B for increasing angular rotation.
8	B	Encoder B output.
9	NM	Encoder North Marker emulation output. Pulse triggered as code passes through zero. Three common pulse widths available.
10	DIR	Indicates direction of rotation of input. Logic HI = increasing angular rotation. Logic LO = decreasing angular rotation.
11	DGND	Digital power ground return.
12	V_{SS}	Negative power supply, −5 V dc ± 5%.
13	V_{DD}	Positive power supply, +5 V dc ± 5%.
14	V_{DD}	Positive power supply, +5 V dc ± 5%. Must be connected to Pin 13.
15	NMC	North marker width control. Internally pulled HI via 50 kΩ nominal.
16	CLKOUT	Internal VCO clock output. Indicates angular velocity of input signals. Max nominal rate = 1.536 MHz. CLKOUT is a 300 ns positive pulse.
17	VEL	Indicates angular velocity of input signals. Positive voltage w.r.t. AGND indicates increasing angle. FSD = 375 rps.
18	REF	Converter reference input. Normally derived from resolver primary excitation. REF = 2 V rms nominal. Phase shift w.r.t. COS and SIN = ±10° max
19	COS LO	COS channel inverting input. Connect to resolver COS LO.
20	COS	COS channel noninverting input. Connect to resolver COS HI output. COS = 2 V rms ± 10%.

ESD SENSITIVITY

The AD2S90 features an input protection circuit consisting of large "distributed" diodes and polysilicon series resistors to dissipate both high energy discharges (Human Body Model) and fast, low energy pulses (Charges Device Model).

Proper ESD precautions are strongly recommended to avoid functional damage or performance degradation. For further information on ESD precautions, refer to Analog Devices *ESD Prevention Manual.*

RESOLVER FORMAT SIGNALS

A resolver is a rotating transformer which has two stator windings and one rotor winding. The stator windings are displaced mechanically by 90° (see Figure 1). The rotor is excited with an ac reference. The amplitude of subsequent coupling onto the stator windings is a function of the position of the rotor (shaft) relative to the stator. The resolver, therefore, produces two output voltages (S3–S1, S2–S4) modulated by the SINE and COSINE of shaft angle. Resolver format signals refer to the signals derived from the output of a resolver. Equation 1 illustrates the output form.

$$S3\text{–}S1 = E_O\ SIN\ \omega t \cdot SIN\theta$$
$$S2\text{–}S4 = E_O\ SIN\ \omega t \cdot COS\theta \quad (1)$$

where: θ = shaft angle
SIN ωt = rotor excitation frequency
E_O = rotor excitation amplitude

Principle of Operation

The AD2S90 operates on a Type 2 tracking closed-loop principle. The output continually tracks the position of the resolver without the need for external convert and wait states. As the transducer moves through a position equivalent to the least significant bit weighting, the output is updated by one LSB.

On the AD2S90, CLKOUT updates corresponding to one LSB increment. If we assume that the current word state of the up-down counter is ϕ, S3–S1 is multiplied by COS ϕ and S2–S4 is multiplied by SIN ϕ to give:

$$E_O\ SIN\ \omega t \cdot SIN\ \theta\ COS\phi$$
$$E_O\ SIN\ \omega t \cdot COS\ \theta\ SIN\phi \quad (2)$$

An error amplifier subtracts these signals giving:

$$E_O\ SIN\ \theta \cdot (SIN\ \theta\ COS\ \phi – COS\ \theta\ SIN\ \phi)$$

or

$$E_O\ SIN\ \omega t \cdot SIN\ (\theta – \phi) \quad (3)$$

where $(\theta – \phi)$ = angular error

A phase sensitive detector, integrator and voltage controlled oscillator (VCO) form a closed loop system which seeks to null sin $(\theta – \phi)$. When this is accomplished the word state of the up/down counter, ϕ, equals within the rated accuracy of the converter, the resolver shaft angle θ.

For more information on the operation of the converter, see Circuit Dynamics section.

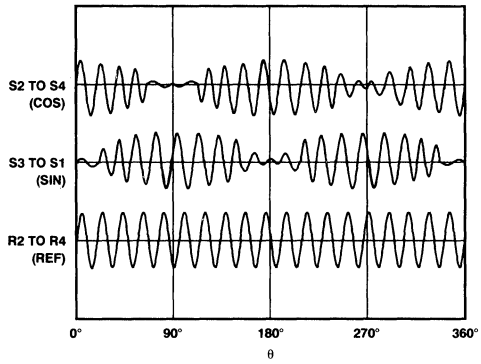


Figure 1. Electrical and Physical Resolver Representation

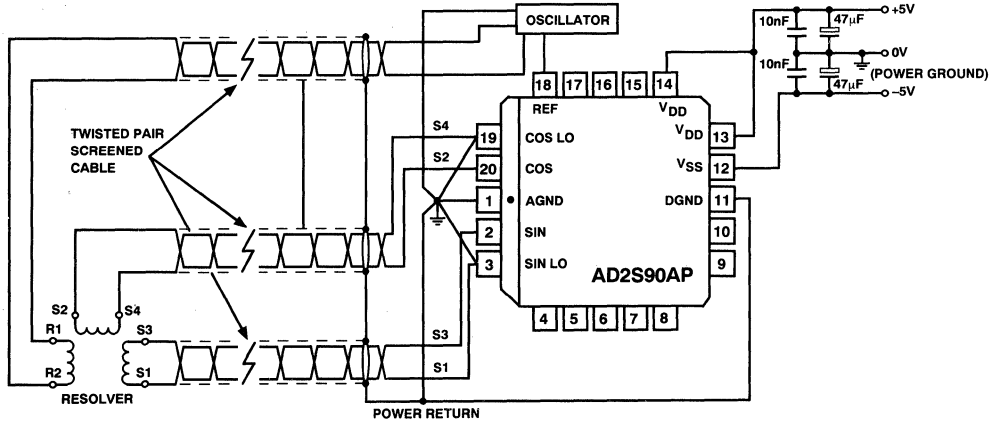

Figure 2. Connecting the AD2S90 to a Resolver

Connecting The Converter

Refer to Figure 2. Positive power supply V_{DD} = +5 V dc ± 5% should be connected to Pin 13 & Pin 14 and negative power supply V_{SS} = −5 V dc ± 5% to Pin 12. **Reversal of these power supplies will destroy the device.** S3 (SIN) and S2 (COS) from the resolver should be connected to the SIN and COS pins of the converter. S1 (SIN) and S4 (COS) from the resolver should be connected to the SINLO and COSLO pins of the converter. The maximum signal level of either the SIN or COS resolver outputs should be 2 V rms ± 10%. The AD2S90 AGND pin is the point at which all analog signal grounds should be star connected. The SIN LO and COS LO pins on the AD2S90 should be connected to AGND. Separate screened twisted cable pairs are recommended for all analog inputs SIN, COS, and REF. The screens should terminate at the converter AGND pin.

North marker width selection is controlled by Pin 15, NMC. Application of V_{DD}, 0 V, or V_{SS} to NMC will select standard 90°, 180° and 360° pulse widths. If unconnected, the NM pulse defaults to 90°. For a more detailed description of the output formats available see the Position Output section.

ABSOLUTE POSITION OUTPUT

SERIAL INTERFACE

Absolute angular position is represented by serial binary data and is extracted via a three wire interface, DATA, $\overline{CS}$ and SCLK. The DATA output is held in a high impedance state when $\overline{CS}$ is HI.

Upon the application of a Logic LO to the $\overline{CS}$ pin, the DATA output is enabled and the current angular information is transferred from the counters to the serial interface. Data is retrieved by applying an external clock to the SCLK pin. The maximum data rate of the SCLK is 2 MHz. To ensure secure data retrieval it is important to note that SCLK should not be applied until a minimum period of 600 ns after the application of a Logic LO to $\overline{CS}$. Data is then clocked out, MSB first, on successive negative edges of the SCLK; 12 clock edges are required to extract the full 12 bits of data. Subsequent negative edges greater than the defined resolution of the converter will clock zeros from the data output if $\overline{CS}$ remains in a low state.

If a resolution of less than 12 bits is required, the data access can be terminated by releasing $\overline{CS}$ after the required number of bits have been read.

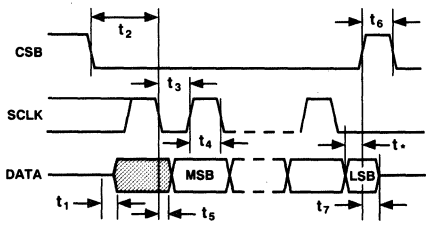

Figure 3. Serial Read Cycle

$\overline{CS}$ can be released a minimum of 100 ns after the last negative edge. If the user is reading data continuously, $\overline{CS}$ can be reapplied a minimum of 250 ns after it is released (see Figure 3).

The maximum read time is given by: (12-bits read @ 2 MHz)
Max RD Time = [600 + (12 × 500) + 600 + 100] = 7.30 µs.

INCREMENTAL ENCODER OUTPUTS

The incremental encoder emulation outputs A, B and NM are free running and are always valid, providing that valid resolver format input signals are applied to the converter.

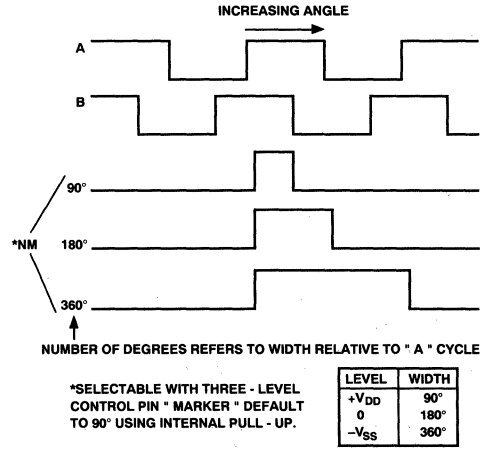

Figure 4. A, B & NM Timing

The AD2S90 emulates a 1024-line encoder. Relating this to converter resolution means one revolution produces 1024 A, B pulses. A leads B for increasing angular rotation. The addition of the DIR output negates the need for external A and B direction decode logic. DIR is HI for increasing angular rotation.

The north marker pulse is generated as the absolute angular position passes through zero. The AD2S90 supports the three industry standard widths controlled using the NMC pin. Figure 4 details the relationship between A, B and NM. The width of NM is defined relative to the A cycle.

Unlike incremental encoders, the AD2S90 encoder output is not subject to error specifications such as cycle error, eccentricity, pulse and state width errors, count density and phase φ.

The maximum speed rating, n, of an encoder is calculated from its maximum switching frequency, f_{max}, and its ppr (pulses per revolution).

$$n = \frac{60 \times f_{max}}{PPR}$$

The AD2S90 A, B pulses are initiated from CLKOUT which has a maximum frequency of 1.536 MHz. The equivalent encoder switching frequency is:

1/4 × 1.536 MHz = 384 kHz (4 updates = 1 pulse)

At 12 bits the ppr = 1024, therefore the maximum speed, n, of the AD2S90 is:

$$n = \frac{60 \times 384000}{1024} = 22500\ rpm$$

This compares favorably with encoder specifications where f_{max} is specified from 20 kHz (photo diodes) to 125 kHz (laser based)

depending on the light system used. A 1024 line laser-based encoder will have a maximum speed of 7300 rpm.

The inclusion of A, B outputs allow the AD2S90 + resolver solution to replace optical encoders directly without the need to change or upgrade existing application software.

VELOCITY OUTPUT

The analog velocity output VEL is scaled to produce 150 rps/V dc ± 15%. The sense is positive V dc for increasing angular rotation. VEL can drive a maximum load combination of 10 kΩ and 30 pF. The internal velocity scaling is fixed.

POSITION CONTROL

The rotor movement of dc or ac motors used for servo control is monitored at all times. Feedback transducers used for this purpose detect either relative position in the case of an incremental encoder or absolute position and velocity using a resolver. An incremental encoder only measures change in position not actual position.

Closed Loop Control Systems

The primary demand for a change in position must take into account the magnitude of that change and the associated acceleration and velocity characteristics of the servo system. This is necessary to avoid "hunting" due to over- or underdamping of the control employed.

A position loop needs both actual and demand position information. Algorithms consisting of proportional, integral and derivative control (PID) may be implemented to control the velocity profile.

A simplified position loop is shown in Figure 5.

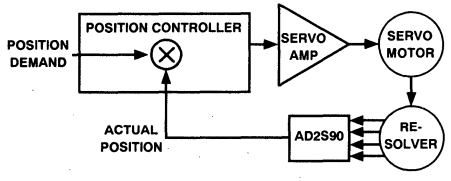

Figure 5. Position Loop

MOTION CONTROL PROCESSES

Advanced VLSI designs mean that silicon system blocks are now available to achieve high performance motion control in servo systems.

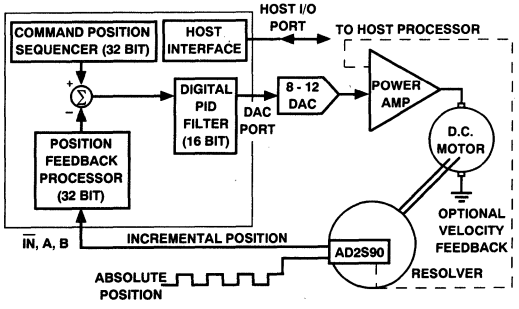

Figure 6. Practical Implementation of the AD2S90

A digital position control system using the AD2S90 is shown in Figure 6. In this system the task of determining the acceleration and velocity characteristics is fulfilled by programming a trapezoidal velocity profile via the I/O port.

As can be seen from Figure 6 encoder position feedback information is used. This is a popular format and one which the AD2S90 emulates thereby facilitating the replacement of encoders with an AD2S90 and a resolver. However, major benefits can be realized by adopting the resolver principle as opposed to the incremental technique.

Incremental feedback based systems normally carry out a periodic check between the position demanded by the controller and the increment position count. This requires software and hardware comparisons and battery backup in the case of power failure. If there is a supply failure and the drive system moves, unless all parts of the system are backed up, a reset to a known datum point needs to take place. This can be extremely hazardous in many applications. The AD2S90 gets round this problem by supplying an absolute position serial data stream upon request, thus removing the need to reset to a known datum.

DSP Interfacing

The AD2S90 serial output is ideally suited for interfacing to DSP configured microprocessors. Figures 7 to 10 illustrate how to configure the AD2S90 for serial interfacing to the DSP. In all cases the AD2S90 is configured for 12-bit operation.

ADSP-2105 Interfacing

Figure 7 shows the AD2S90 interfaced to an ADSP-2105. The on-chip serial port of the ADSP-2105 is used in alternate framing receive mode with internal framing (internally inverted) and internal serial clock generation (externally inverted) options selected. In this mode the ADSP-2105 provides a $\overline{CS}$ and a serial clock to the AD2S90. The serial clock is inverted to prevent timing errors as a result of both the AD2S90 and ADSP-2105 clock data on the negative edge of SCLK. The first data bit is void; 12-bits of significant data then follow on each consecutive negative edge of the clock. Data is clocked from the AD2S90 into the data receive register of the ADSP-2105. This is internally set to 13 bit (12 bits and one "dummy" bit) when 13 bits are received. The serial port automatically generates an internal processor interrupt. This allows the ADSP-2105 to read 12 significant bits at once and continue processing.

The ADSP-2101, ADSP-2102, ADSP-2111 and 21msp50 can all interface to the AD2S90 with similar interface circuitry.

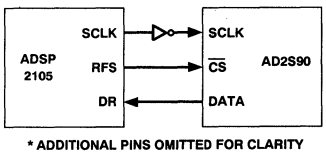

Figure 7. ADSP-2105/AD2S90 Serial Interface

16

TMS32020 Interfacing

Figure 8 shows the serial interface between the AD2S90 and the TMS32020. The interface is configured in alternate internal framing, external clock (externally inverted) mode. Sixteen bits of data are clocked from the AD2S90 into the data receive register (DDR) of the TMS32020. The DRR is fixed at 16 bits. To obtain the 12-significant bits, the processor needs to execute three right shifts. (First bit read is void, the last three will be zeros). When 16 bits have been received by the TMS32020, it generates an internal interrupt to read the data from the DRR.

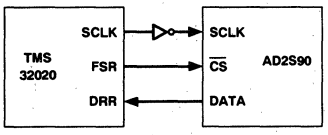

Figure 8. TMS32020/AD2S90 Serial Interface

DSP56000 Interface

Figure 9 shows a serial interface between the AD2S90 and the DSP56000. The DSP in configured for normal mode synchronous operation with gated clock with SCK and SCI as outputs. SCI is applied to $\overline{CS}$.

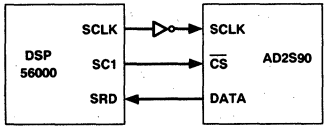

Figure 9. DSP56000/AD2S90 Serial Interface

The DSP56000 assumes valid data on the first falling edge of SCK. SCK is inverted to ensure that the valid data is clocked in after one leading bit. The receive data shift register (SRD) is set for a 13-bit word.

When this register has received 13 bits of data, it generates an internal interrupt on the DSP56000 to read the 12-bits of significant data from the register.

NEC7720 Interface

Figure 10 shows the serial interface between the NEC7720 and the AD2S90. The NEC7720 expects data on the rising edge of its SCK output, and therefore unlike the previous interfaces no inverter is required to clock data into the SI register. There is no need to ignore the first data bit read. $\overline{SIEN}$ is used to Chip Select the AD2S90 and frame the data. The SI register is fixed at 16 bits, therefore, to obtain the 12-significant bits the processor needs to execute four right shifts. Once the NEC7720 has read 16 bits, an internal interrupt is generated to read the internal contents of the SI register.

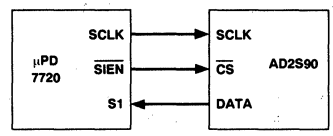

Figure 10. μPD7720/AD2S90 Serial Interface

EDGE TRIGGERED 4 × DECODING LOGIC

In most data acquisition or control systems the A, B incremental outputs must be decoded into absolute information, normally a parallel word, before they can be utilized effectively.

To decode the A, B outputs on the AD2S90 the user must implement a 4 × decoding architecture. The principle states that one A, B cycle represents 4 LSB weighted increments of the converter (see Equation 4).

$$Up = (\uparrow A) \cdot B + (\downarrow A) \cdot B + (\uparrow B) \cdot A + (\downarrow B) \cdot A$$

$$Down = (\uparrow A) \cdot B + (\uparrow A) \cdot B + (\uparrow B) \cdot A + (\downarrow B) \cdot A \quad (4)$$

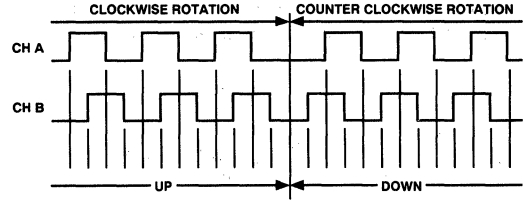

Figure 11. Principles of 4 × Decoding

The algorithms in Equation 4 can be implemented using the architecture shown in Figure 12. Traditionally the direction of the shaft is decoded by determining whether A leads B. The AD2S90 removes the need to derive direction by supplying a direction output state which can be fed straight into the up-down counter.

For further information on this topic please refer to the application note "Circuit Applications of the AD2S90 Resolver-to-Digital Converters."

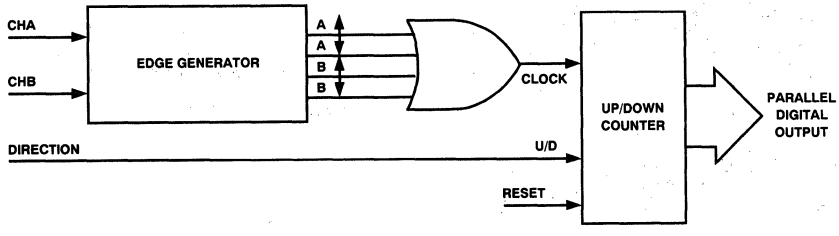

Figure 12. 4 × Decoding Incremental to Parallel Conversion

REMOTE MULTIPLE SENSOR INTERFACING

The DATA output of the AD2S90 is held in a high impedance state until $\overline{CS}$ is taken LO. This allows a user to operate the AD2S90 in an application with more than one converter connected on the same line. Figure 13 shows four resolvers interfaced to four AD2S90s. Excitation for the resolvers is provided locally by an oscillator.

SCLK, DATA and two address lines are fed down low loss cables suitable for communication links. The two address lines are decoded locally into $\overline{CS}$ for the individual converters. Data is received and transmitted using transmitters and receivers.

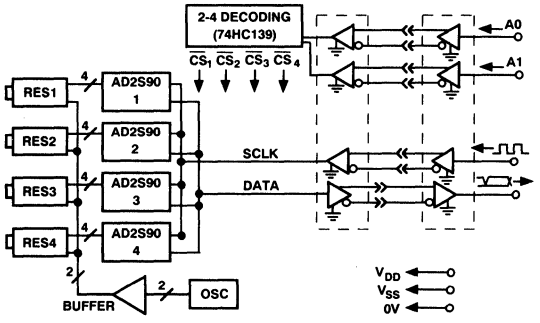

Figure 13. Remote Sensor Interfacing

CIRCUIT DYNAMICS/ERROR SOURCES

Transfer Function

The AD2S90 operates as a Type 2 tracking servo loop. An integrator and VCO/counter perform the two integrations inherent in a Type 2 loop.

The overall system response of the AD2S90 is that of a unity gain second order low-pass filter, with the angle of the resolver as the input and the digital position data as the output. Figure 14 illustrates the AD2S90 system diagram.

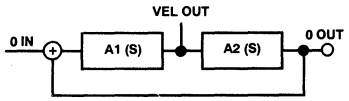

Figure 14. AD2S90 Transfer Function

The open loop transfer function is given by;

$$\frac{\theta_{OUT}}{\theta_{IN}} = \frac{K_1 K_2}{s^2} \frac{(1 + st_1)}{1 + st_2} \quad (5)$$

where:

$$A_1(s) = \frac{K_1}{s} \frac{1 + st_1}{1 + st_2} \qquad \begin{matrix} t_1 = 1.0\text{ ms} \\ t_2 = 90\ \mu\text{s} \end{matrix} \quad (6)$$

$$A_2(s) = \frac{K_2}{s} \qquad \begin{matrix} K_1 = 364\text{s}^{-2} \\ K_2 = 200{,}000\text{s}^{-2} \end{matrix} \quad (7)$$

The AD2S90 acceleration constant is given by:

$$K_a = K_1 \cdot K_2 = 72.8 \times 10^6\ sec^{-2} \quad (8)$$

The AD2S90's design has been optimized with a critically damped response. The closed-loop transfer function is given by:

$$\frac{\theta_{OUT}}{\theta_{IN}} = \frac{1 + st_1}{1 + st_1 + \frac{s_2}{K_1 K_2} + \frac{s_3 t_2}{K_1 K_2}} \quad (9)$$

The normalized gain and phase diagrams are given in Figures 15 and 16.

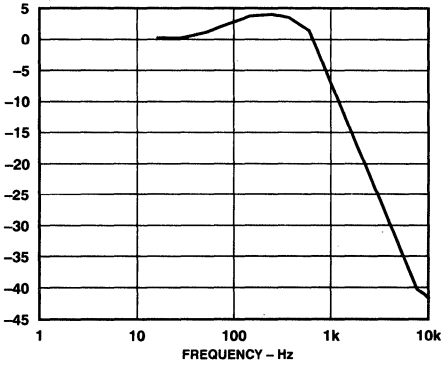

Figure 15. AD2S90 Gain Plot

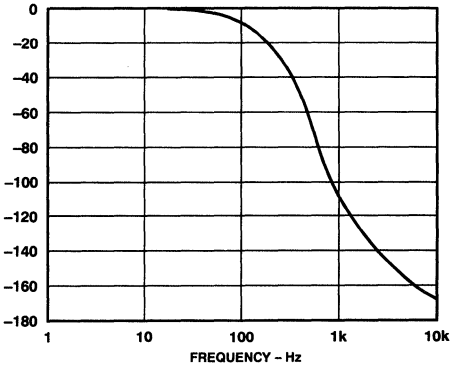

Figure 16. AD2S90 Phase Plot

16

The small step response is given in Figure 17, and is the time taken for the converter to settled to within 1 LSB.

ts = 7.00 ms (12-bit resolution)

The large step response (steps>20°) applies when the error voltage will exceed the linear range of the converter. Typically it will take three times longer to reach the first peak for a 179° step.

In response to a velocity step [VELOUT/(dθ/dt)] the velocity output will exhibit the same response characteristics as outlined above.

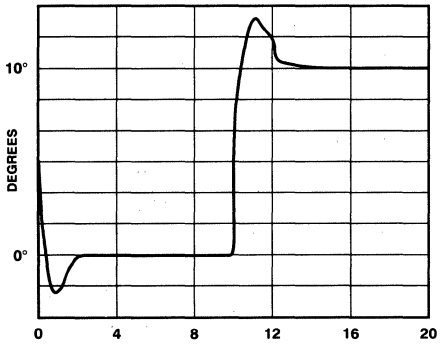

Figure 17. Small Step Response

SOURCES OF ERROR

Acceleration Error

A tracking converter employing a Type 2 servo loop does not suffer any velocity lag, however, there is an additional error due to acceleration. This additional error can be defined using the acceleration constant K_a of the converter.

$$K_a = \frac{Input\ Acceleration}{Error\ in\ Output\ Angle} \tag{10}$$

The numerator and denominator's units must be consistent. *K_a does not define maximum input acceleration,* only the error due to its acceleration. The maximum acceleration allowable before the converter loses track is dependent on the angular accuracy requirements of the system.

$$Angular\ Error \times K_a = degrees/sec2 \tag{11}$$

K_a can be used to predict the output position error for a given input acceleration. The AD2S90 has a fixed $K_a = 72.8 \times 10^6$ sec^{-2} if we apply an input accelerating at 100 revs/sec^2 in 12-bit mode.

$$Error\ in\ LSBs = \frac{Input\ Acceleration\ [LSB/sec2]}{K_a\ [sec^{-2}]}$$

$$= \frac{100\ [rev/sec2] \times 2^{12}}{72.8 \times 10^6} = 5.62 \times 10^{-3}\ LSBs \tag{12}$$

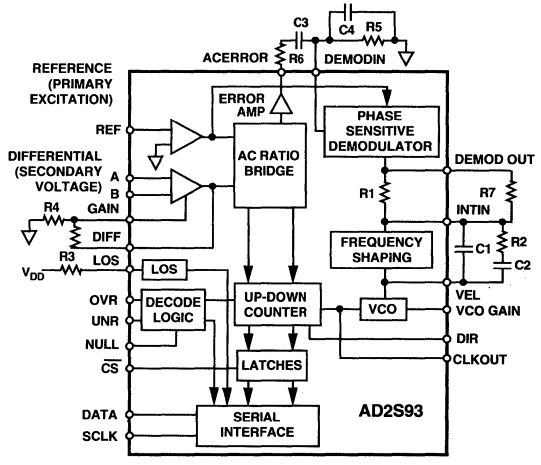
FUNCTIONAL BLOCK DIAGRAM



GENERAL DESCRIPTION

The AD2S93 is a complete 14-bit resolution tracking LVDT-to-digital converter. A Type II tracking loop is employed to track the A–B input and produce a digital output equal to (A–B)/(REF/2), where REF is a fixed amplitude ac reference phase coherent with the A–B input. This allows the measurement of any 2-, 3-, 4- and 5-wire LVDT or linear amplitude modulated input. The operating frequency range is from 360 Hz to 10 kHz with user definable bandwidth set externally within a range of 45 Hz to 1250 Hz.

The AD2S93 has a 16-bit serial output. The MSB (LOS), read first, indicates a loss of the signal A, B, or reference inputs to the converter or transducer. The second and third MSBs are flags indicating whether [–REF/2 (UNR) ≤ A–B ≤ +REF/2 (OVR)] is outside the linear operating range of the converter. The displacement data is presented as 13-bit offset binary giving a ±12-bit operating range. LOS, OVR and UNR are pinned out on the device, in addition a NULL flag is available which is set when (A–B) = 0.

Absolute displacement information is accessed when $\overline{CS}$ is taken LO followed by the application of an external clock (SCLK) with a maximum rate of 2 MHz. Data is read MSB first. When $\overline{CS}$ is high the DATA output is high impedance; this allows daisy chaining of more than one converter onto a common bus.

The A, B differential input allows the user to scale the A, B inputs between 1 and 10. This enables the user to accurately set up the inputs matching the REF input to the DIFF output. The DIFF output is the resultant A–B. The AD2S93 operates using ±5 V ± 5% power supplies and is fabricated on Analog Devices' linear compatible CMOS process (LC²MOS). The (LC²MOS) is a mixed technology process that combines precision bipolar circuits with low power logic.

PRODUCT HIGHLIGHTS

Complete LVDT-to-Digital Interface. The AD2S93 provides the complete solution for digitizing LVDT signals to 14-bit resolution.

Serial 16-Bit Output Data. One 16-bit read from the AD2S93 determines input signal continuity (LOS), over and underrange detection and 13 bits of offset binary displacement information.

High Accuracy Grade in Low Cost Package. 0.05% and 0.1% integral linearity over the full –40°C to +85°C operating temperature range.

Uncommitted Differential Input. Allows configuration of 2-, 3-, 4- and 5-wire LVDTs.

Multiple Converter Interfacing. High impedance data output and a simple three-wire interface reduces cabling and eliminates bus contention.

Low Power. 70 mW power consumption (typ).

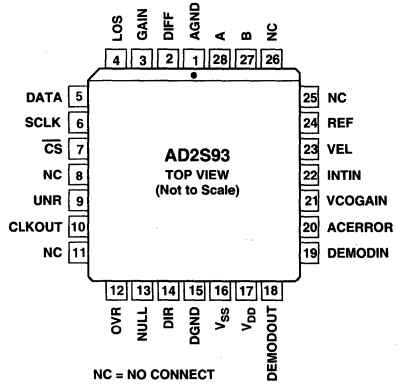
NULL, DIR, CLKOUT, DATA .... –0.3 V to V_{DD} + 0.3 V
Operating Temperature Range
Industrial (A, B) .....–40°C to +85°C
Lead Temperature (Soldering 10 sec) ..... +300°C
Power Dissipation to +75°C ..... +100 mW
Derates above +75°C by ..... 10 mW/°C

*Stresses above those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. This is a stress rating only and functional operation of the device at these or any other conditions above those indicated in the operational section of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.



ORDERING GUIDE

Model	Temperature Range	Linearity	Package Option*
AD2S93AP	–40°C to +85°C	0.1%	P-28A
AD2S93BP	–40°C to +85°C	0.05%	P-28A

*For outline information see Package Information section.

PIN DESIGNATIONS

Pin No.	Mnemonic	Description
1	AGND	Analog Ground.
2	DIFF	Output of Signal Input Preamplifier.
3	GAIN	Connect GAIN Pin to DIFF for nominal × 1. Gains greater than 1 can be resistively scaled. Do not leave unconnected.
4	LOS	Denotes A or B lines loss of connection and/or loss of reference to transducer or converter.
5	DATA	16-bit serial data output 13 bits of absolute position information plus overrange and underrange plus LOS.
6	SCLK	Serial Clock. Maximum rate = 2 MHz.
7	$\overline{CS}$	Chip Select. Loads serial interface with current positional information and enable output.
9, 12	UNR, OVR	Two pins that denote whether the input signals are underrange or overrange.
10	CLKOUT	Updates every LSB.
13	NULL	Denotes Null Position.
14	DIR	Indicates direction. DIR is HI for positive displacement and LO for negative displacement.
15	DGND	Digital Ground.
16	V_{SS}	Negative Power Supply –5.0 V dc ± 5%.
17	V_{DD}	Positive Power Supply +5.0 V dc ± 5%.
18	DEMODOUT	Output of the Phase Sensitive Demodulator.
19	DEMODIN	Input to Phase Sensitive Demodulator.
20	ACERROR	AC Error Output.
21	VCO GAIN	Sets the VCO gain internally. Connect to VEL for 2400 LSB/s. Disconnect for 800 LSB/s.
22	INTIN	Determines system dynamics connect C and RC (serial) parallel combination across INTIN and VEL to determine loop dynamics.
23	VEL	Analog Velocity Output.
24	REF	Single ended input for fixed amplitude reference.
27, 28	B, A	Uncommitted differential inputs for the A, B signal inputs.

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the AD2S93 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

GLOSSARY OF TERMS

INTEGRAL LINEARITY

Integral linearity deviation as a percent of full scale. A 0.1% deviation is equivalent to 8-LSB change on the output.

Gain

The converter gain is the maximum variation in the ratio of A–B/REF/2 to the maximum digital input.

Output Offset

The output offset is the digital output code when the analog input signal A–B = 0.

Overrange (OVR)

OVR goes high when A–B is in phase with REF and larger than REF/2.

Underrange (UNR)

UNR goes high when A–B is out of phase with REF and larger than REF/2.

PRINCIPLE OF OPERATION

The AD2S93 is based on a Type 2 tracking closed-loop principle. The output tracks the position of the LVDT without the need for external convert and wait states. As the transducer moves through a position equivalent to the least significant bit weighting, the output is updated by one LSB. On the AD2S93, CLKOUT updates corresponding to one LSB increment. Figure 1 illustrates the principle of operation.

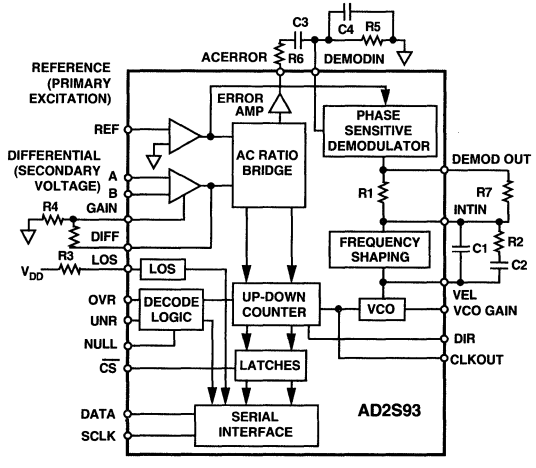


Figure 1. Functional Block Diagram

Because the conversion depends on the ratio of the input signals (ratiometric ac bridge), the AD2S93 is remarkably tolerant of input amplitude and frequency. This, combined with the definable Type 2 tracking closed-loop guarantees the AD2S93's repeatability for a given input. A phase sensitive detector, integrator and voltage controlled oscillator (VCO) form a closed loop system which seeks to null the output of the ACERROR. When this is accomplished the word state of the up/down counter equals within the rated accuracy of the converter, the LVDT position output.

For more information on the operation of the converter, see "Circuit Dynamics" section.

DATA FORMAT

OPERATING RANGE

The AD2S93 operating range is defined in Figure 2. The linearity and specified operating range of the converter is the central two 12-bit quadrants through zero. The corresponding input relationship is $-REF/2 \le A–B \le +REF/2$, ($\pm$ is used to denote phase coherency). The sign bit is low for inputs with A–B in phase with REF. The two remaining 12-bit quadrants are used to denote over (OVR) and underrange (UNR). OVR goes high when A–B is in phase with REF and larger than REF/2. UNR goes high when A–B is out of phase with REF and larger than REF/2. LOS is an open drain output which pulls high when A and/or B are removed or REF is removed (see "Inbuilt Diagnostics"), or A + B is less than 100 mV.

SCALING THE INPUTS

In order to match the LVDT output to the AD2S93 output, the inputs to the AD2S93 need to be scaled. The operating range is illustrated in Figure 2. The AD2S93 operates across $\pm$12-bit range where the remaining 12-bit quadrants are used to denote overrange and underrange. The output position word is a function of the ratio between A–B and V_{REF} (see Figure 2) where:

$$\pm FSR = \frac{(A-B)}{V_{REF}/2}$$

16

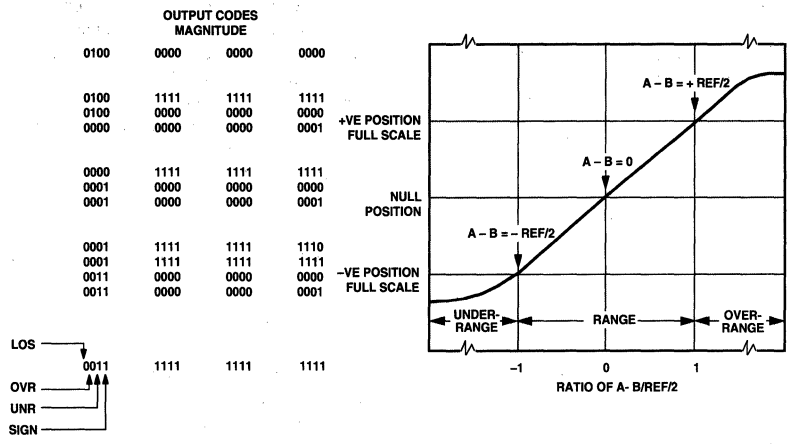

Figure 2. Output Code Format

If the maximum operating stroke of an LVDT yielded a 1 V rms A–B output, the weighting of the LVDT to AD2S93 digital output would be:

$$\frac{\textit{Input Signal Full Scale}}{\textit{Full-Scale Operating Range } (\pm 2^{12})}$$

$$\frac{1 \times 2\sqrt{2}}{2^{13}}$$

$$\textit{Input Scaling} = 345\ \mu V/LSB$$

This can be equated directly to the LVDT sensitivity specification in mm/v/v.

Note: The overrange and underrange quadrants can be utilized by decoding the overrange and underrange MSBs and decoding the 12 magnitude bits. This will increase the operating range of the AD2S93 accordingly. However, if the input A–B > V_{REF} then the converter will lose track of the input and will only regain track when the input signal returns to within the operating range of the converter.

INPUT GAIN

Since the transformation ratio of an LVDT or RVDT from excitation voltage to signal voltage can be 1:0.15, provision for gain scaling has been provided. The gain can, therefore, be selected to ensure that the full-scale output of converter represents the maximum stroke position of the transducer.

The gain setting is accomplished by connecting Pin 2, (DIFF) and Pin 3 (GAIN) together (unity gain) or connecting two resistors as shown in Figure 3.

The gain of the input stage is calculated using the following equation:

$$\frac{DIFF(A-B)}{(A-B)\,IN} = 1 + \frac{R_3}{R_4}$$

e.g., For a gain of 5, R3 = 12 kΩ, R4 = 3 kΩ
For a gain of 10, R3 = 18 kΩ, R4 = 2 kΩ

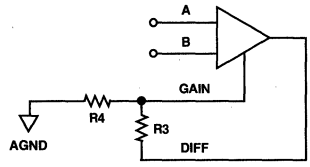

Figure 3. Pre-Amp Gain Block

SETTING THE CONVERTER BANDWIDTH

The AD2S93 bandwidth is set by placing three external components, C1, C2, and R2, around the integrator as illustrated by the figure below.

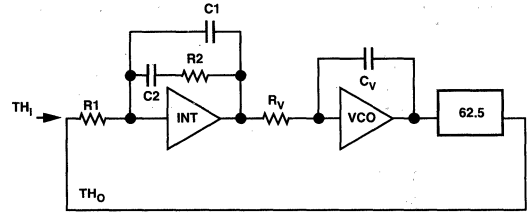

Figure 4. Integrator and VCO

Before the bandwidth can be set, the corresponding VCO gain setting must be determined. The VCO gain is directly related to the slew rate of the converter. This is set internally to two different rates defined internally by R_V.

Typical converter slew rates are defined below,

G (1) = 2400 *LSB/ms–Mode* 1
G (2) = 800 *LSB/ms–Mode* 2

Calculation of the component values for the bandwidth is detailed below. For more detailed information on component value selection for the AD2S93, please consult the "Passive Component Selection and Dynamic Modeling Software for the AD2S93 LVDT-to-Digital Converter."

VCO Gain G (1) Mode 1
The available bandwidth with this option is from 0.5 kHz to 1.25 kHz.

$$F_{REF} > 8 \times Fo$$
$$C1 = 1/(800 \times Fo^2)$$
$$C2 = 8 \times C1$$
$$R2 = 45 \times Fo$$

Where F_{REF} is the reference frequency, Fo is the closed-loop 3 dB point.

VCO Gain G (2) Mode 2
The available bandwidth with this option is from 45 Hz to 500 Hz.

$$F_{REF} > 8 \times Fo$$
$$C1 = 1/(2400 \times Fo^2)$$
$$C2 = 8\ C1$$
$$R2 = 45 \times Fo$$

Where F_{REF} is the reference frequency, Fo is the closed-loop 3 dB point.

INTERFACING TO THE AD2S93 (SEE "TIMING CHARACTERISTICS")
The absolute position information is extracted via a three-wire interface, DATA, $\overline{CS}$ and SCLK. The DATA output is held in a high impedance state when $\overline{CS}$ is high.

Upon the application of logic low to the $\overline{CS}$ pin, the DATA is enabled and the current position information is transferred from the counters to the serial interface. Data is retrieved by applying an external clock to the SCLK pin. The maximum data rate of the SCLK is 2 MHz. To ensure secure data retrieval, it is important to note that SCLK should not be applied until a minimum period of 600 ns after the application of logic low to $\overline{CS}$. Data is then clocked out on successive positive edges of SCLK: 16 clock edges are required to extract the entire data word. Subsequent positive edges greater than the defined resolution of the converter will clock zeros from the data output if $\overline{CS}$ remains in a low state. The format of the data read is shown in Table I.

Table I.

	DB0	DB1	DB2	DB3	DATA DB4–D15 MSB LSB
Function	LOS	OVR	UNR	SIGN	MAGNITUDE

If less than the full 16-bit word is required, then the data read can be terminated by releasing $\overline{CS}$ after the required number of bits have been read.

$\overline{CS}$ can be released a minimum of 100 ns after the last positive edge. If the user is reading data continuously, $\overline{CS}$ can be reapplied after a minimum of 600 ns after it is released. The minimum repetitive read time of the same converter is given by (16 bits read @ 2 MHz). Min RD Time = [600 + (16 × 500) + 600] = 9.2 µs.

IN-BUILT DIAGNOSTICS
The first three bits read from the serial interface preceding the sign and magnitude data can be used to determine whether the data is valid or not. Over and underrange (OVR, UNR) denote the two extremes of the LVDT stroke where linearity of the LVDT may degrade. Loss of signal LOS is an open drain output which pulls high (12 kΩ pull up) when one of the following conditions is satisfied:

1. A and/or B is disconnected.
2. REF is disconnected.

Note: LOS has a response time of 50 ms max to the conditions stated above, see "Specifications."

CONNECTING THE CONVERTER
Positive power supply V_{DD} = +5 V dc ± 5% should be connected to Pin 17 and negative power supply V_{SS} = –5 V dc ± 5% to Pin 16. *Reversal of these power supplies will destroy this device.* For LVDT connections to the converter please refer to Figures 5 through 7. On all connections, the maximum input reference signal V_{REF} = 2.0 V rms ± 10%. To operate within the standard operating range, A–B should not exceed 1.0 V rms ± 10%. The AD2S93 AGND point is the point at which all analog signal grounds should be connected. Ground returns from the LVDT should be connected to AGND. The AD2S93 DGND pin should be connected to the AD2S93 AGND pin. Ancillary Digital circuitry must be connected to the Star Point and not to the AD2S93 AGND pin.

In all cases, the AD2S93 has been configured with the following dynamics.

Reference Frequency	*5 kHz*
3 dB Bandwidth	*625 Hz*

Vco Gain is set in MODE 1 where VCO GAIN is connected to VEL.

Using the procedure described in "setting the converter bandwidth" the following preferred values (E12 series) were calculated:

$$C1 = 3.3\ nF$$
$$C2 = 27\ nF$$
$$R2 = 27\ k\Omega$$

CALCULATING HF FILTER (C3, C4, R5, R6)

$$15\ k\Omega \le R5 = R6 \le 56\ k\Omega$$

$$C3 = C4 = \frac{1}{2\pi\ R5\ F_{REF}}$$

So, C3 = 1 nF, R5 = R6 = 33 kΩ, C4 = 1 nF and in all cases R7 = 15 kΩ.

Half-Bridge Type LVDT Connection
In this method of connection, it is necessary to add two additional bridge completion resistors R_C and R_C, in order to derive a reference for the AD2S93. In selecting the bridge completion resistor, it is important to remember that mismatch between R_{C1} and R_{C2} will cause nonzero errors at null. If two LVDTs are being used for differential measurements, the resistors can be replaced by the second LVDT.

16

Three- or Four-Wire LVDT Connection

In this method of connection, shown in Figure 6, the converters digital output is proportional to the ratio:

$$\frac{(A-B)}{(A+B)/2}$$

where A and B are the individual LVDT secondary output voltages. Inspection of Figure 6 should demonstrate why this relationship is true. (A–B) is simply the voltage across the series connected secondaries of the LVDT and is applied to the A, B input to the converter. (A + B)/2 is effectively the average of the two secondary voltages as computed by the balanced bridge completion resistors and the grounding of the secondary center-tap.

Note: This method of connection is appropriate only for where (A + B) is a constant, independent of LVDT position. Any lack of constancy in (A + B) will be reflected as an additional non-linearity in the output. It is up to the user to determine if (A + B) is sufficiently constant over the particular stroke length employed.

This method will usually restrict the usable LVDT range to half of its full range. The restriction can be eliminated, however, by attenuating DIFF by a factor of 2 or increasing V_{REF} by a factor of 2. This connection method has the tremendous advantage of being insensitive to temperature related phase shifts and excitation oscillator instability effects usually associated with more conventional LVDT conversion systems.

As in the case of the half-bridge type LVDT connection, R_{C1} and R_{C2} are the bridge completion resistors and are matched to a degree sufficient to ensure that the digital output representing the null position does not vary from the LVDT's natural null position. If null adjustment is required, a potentiometer can be used in place of the common connection between the two resistors.

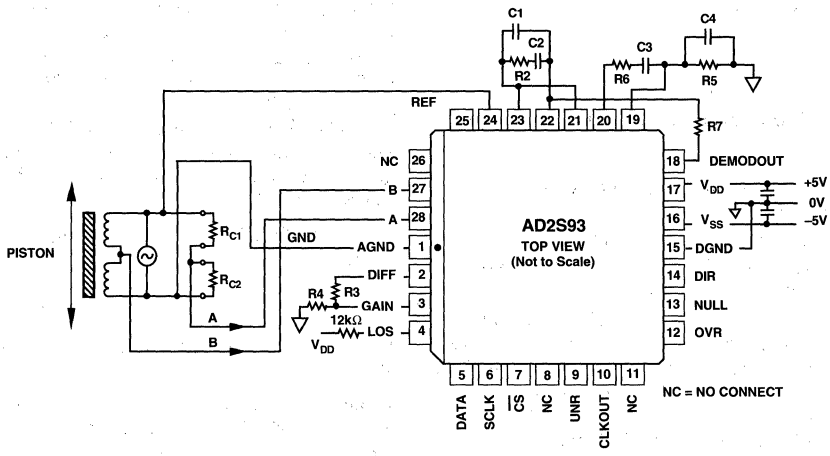

Figure 5. Half-Bridge Type LVDT Connection

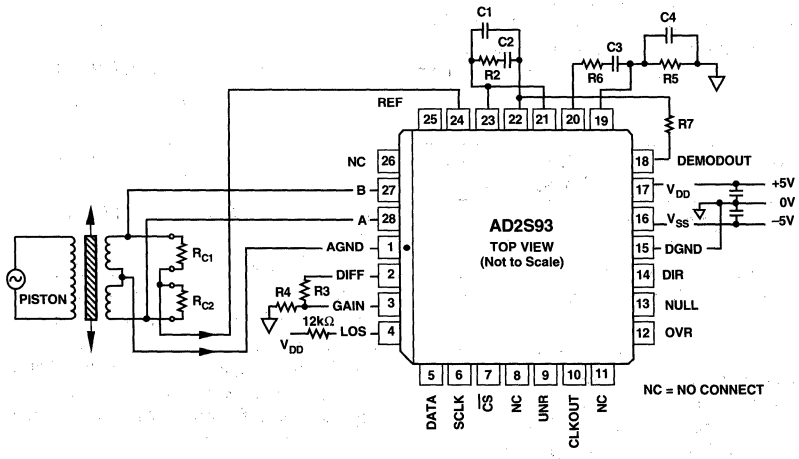

Figure 6. Three- or Four-Wire LVDT Connection

Two-Wire LVDT Connection

This method should be used in cases where the sum of the LVDT secondary output voltages (A + B) is not constant with LVDT displacement over the desired stroke length. This method of connection, shown in Figure 7, still maintains the ratiometric operation and the insensitivity to variations in reference amplitude and frequency. However, the phase shift between V_{REF} and V1 should be minimized to maintain accuracy (see Section "PHASE SHIFT AND QUADRATURE EFFECTS"). Suggested phase compensation circuits are shown in Figure 7.

PHASE SHIFT AND QUADRATURE EFFECTS

Reference to signal phase shift can be high in LVDTs, sometimes in the order of 70 degrees. If the converter is connected as in Figures 5 and 6, any effects due to this phase shift are minimized. This connection method, therefore, provides outstanding benefits.

The additional gain error caused by reference to signal phase shifts is given by:

$$(1 - \cos\theta) \times 100\% \text{ of FSR}$$

where

θ = *phase shift between V_{REF} and DIFF.*

When the phase shift between V_{REF} and V1 is zero, additional quadrature on the signal will have no effect on the converter. This is another benefit of the conversion method. For example, when a REF lags (A–B) by approximately 10°, the gain error is approximately 1%. When (A–B) lags REF by approximately 10°, the gain error is approximately 2%.

REMOTE MULTIPLE SENSOR INTERFACING

The DATA output of the AD2S93 is held in a high impedance state until $\overline{CS}$ is taken LO. This allows a user to operate the AD2S93 in an application with more than one converter connected on the same line. Figure 8 shows four LVDTs interfaced to four AD2S93s. Excitation for the LVDT is provided locally by an oscillator.

SCLK, DATA and two address lines are fed down low loss cables suitable for communication links. The two address lines are decoded locally into $\overline{CS}$ for the individual converters. Data is received and transmitted using transmitters and receivers.

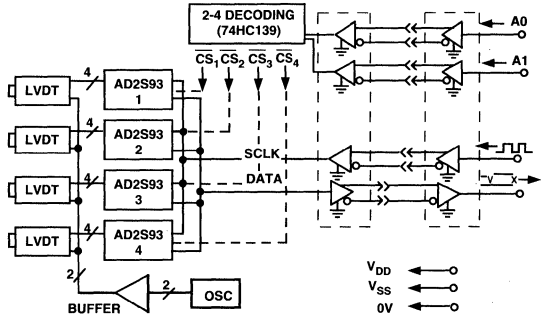

Figure 8. Remote Sensor Interface

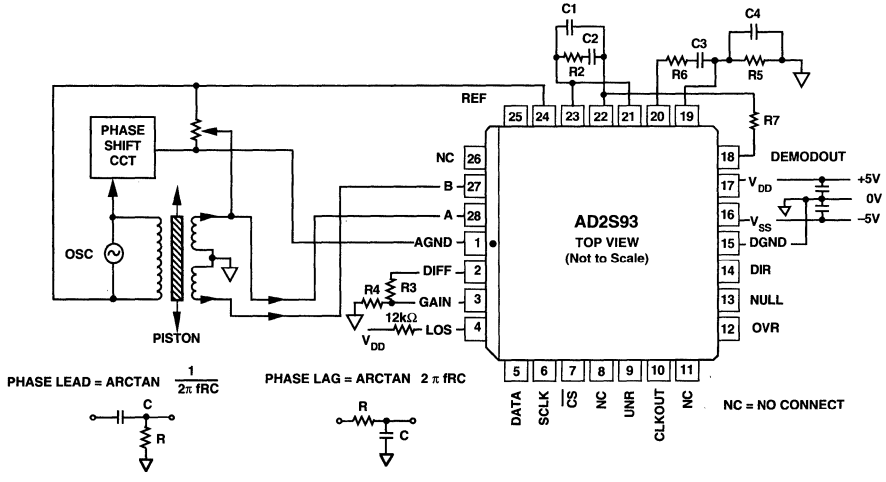

Figure 7. Two-Wire LVDT Connection

CIRCUIT DYNAMICS/ERROR SOURCES

TRANSFER FUNCTION

The AD2S93 operates as a Type 2 tracking servo loop. An integrator and VCO/counter perform the two integrations inherent in a Type 2 loop.

The overall system response of the AD2S93 is that of a unity gain second order low-pass filter, with the position of the LVDT as the input and the digital position data as the output. Figure 9 illustrates the AD2S93 system diagram.

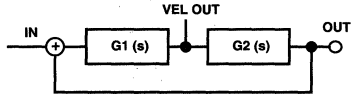

Figure 9. AD2S93 Transfer Function

Note: The AD2S93 has been configured with the following dynamics.

Reference Frequency	10 kHz
3 dB Bandwidth	1250 Hz

VCO Gain is set in MODE 1 where VCOGAIN is connected to VEL.

Using the procedure described in "SETTING THE CONVERTER BANDWIDTH," the following preferred values (E12 series) were calculated:

$C1 = 820$ pF
$C2 = 6.8$ nF
$R2 = 56$ kΩ

C3 = C4 = 470 pF, R7 = 15 kΩ, R5 = R6 = 33 kΩ, C4 = 470 pF

The open-loop transfer function is given by:

$$G1(s) = \frac{K_1}{s} \cdot \frac{1+st_1}{1+st_2}$$

$$G2(s) = \frac{K_2}{s}$$

where:

$$t_2 = R_2\left(\frac{C_1 \times C_2}{C_1 + C_2}\right)$$

$t_1 = R_2 C_2$

and:

$$K_1 = \frac{4\times10^{-3}}{25\times10^{3}} = 160\times10^{-9}\times\frac{1}{C_1+C_2} = 21$$

$$K_2 = \frac{4}{R_V \times C_V}$$

Note A_2 has two values depending on which mode is being used

$K_{2\,(MODE1)} = 640 \times 10^3$
$K_{2\,(MODE2)} = 160 \times 10^3$

The AD2S93 acceleration constant is given by:

$$K_a = K_1 \times K_2$$

Therefore in the example given,

$$K_a = K_1 \times K_2 = 21 \times 640 \times 10^3 = 13.44 \times 10^6\ s^{-2}$$

The AD2S93's design has been optimized with a critically damped response. The closed-loop transfer function is given by:

$$\frac{\theta_{OUT}}{\theta_{IN}} = \frac{1+st_1}{1+st_1+\frac{s_2}{K_1K_2}+\frac{s_3t_2}{K_1K_2}} \quad \frac{\theta_{OUT}}{\theta_{IN}} = \frac{K_1K_2}{s^2}\,\frac{(1+st_1)}{1+st_2}$$

The normalized gain and phase diagrams are given in Figures 10 and 11 with a bandwidth of 1.25 kHz.

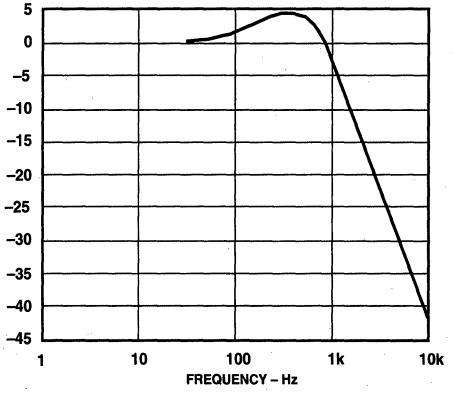

Figure 10. AD2S93 Gain Plot

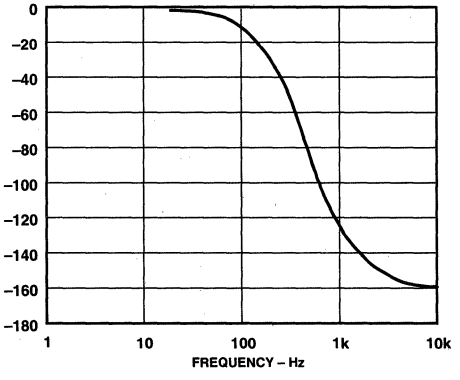

Figure 11. AD2S93 Phase Plot

The small step response is given in Figure 12, and is the time taken for the converter to settled to within 1 LSB.

ts = 7 ms (14-bit resolution)

The large step response (steps >5% of FSR) applies when the error voltage will exceed the linear range of the converter. Typically it will take three times longer to reach the first peak FSR.

In response to a velocity step [VELOUT/(dθ/dt)] the velocity output will exhibit the same response characteristics as outlined above.

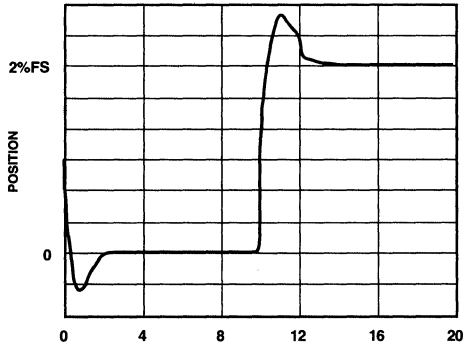

Figure 12. Small Step Response

SOURCES OF ERROR

ACCELERATION ERROR

A tracking converter employing a Type 2 servo loop does not suffer any velocity lag, however, there is an additional error due to acceleration. This additional error can be defined using the acceleration constant K_a of the converter.

$$K_a = \frac{input\ acceleration}{position}$$

The numerator and denominator's units must be consistent. *K_a does not define maximum input acceleration,* only the error due to its acceleration. The maximum acceleration allowable before the converter loses track is dependent on the positional accuracy requirement of the system.

$$Position\ Error \times K_a = LSB/sec^2$$

K_a can be used to predict the output position error for a given input acceleration. The AD2S93 in the example has a $K_a = 13.44 \times 10^6$ sec^{-2} if we apply an input accelerating at 100×2^{14} LSB/sec^2.

$$Error\ in\ LSBs = \frac{input\ acceleration\left[LSB/sec^2\right]}{K_a\left[sec^{-2}\right]}$$

$$= \frac{100 \times 2^{14}}{13.44 \times 10^6} = 0.12\ LSBs$$

Programmable Oscillator

AD2S99

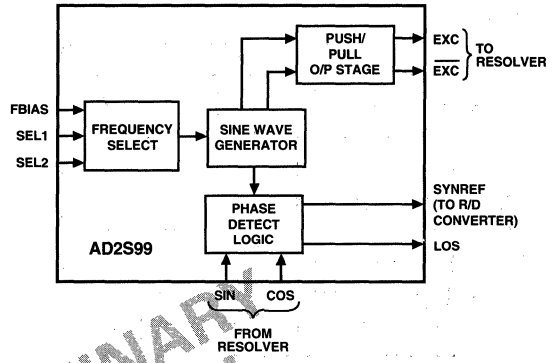
FEATURES

Programmable Sinusoidal Oscillator
Synthesized Synchronous Reference Output
Programmable Output Frequency Range: 2 kHz – 20 kHz
Wide Power Supply Range
"Loss-of-Signal" Indicator
20-Pin PLCC Package
Low Cost

APPLICATIONS

Primary Excitation of:
Resolvers
Synchros
LVDTs
RVDTs
Pressure Transducers
Load Cells
Inductosyns
AC Bridges

FUNCTIONAL BLOCK DIAGRAM



GENERAL DESCRIPTION

The AD2S99 is a programmable sinusoidal oscillator available in a 20-pin PLCC package, with an operating temperature range of –40°C to +85°C.

The AD2S99 provides a sine wave excitation output for resolvers and a wide variety of ac transducers. The AD2S99 also provides a synthesized reference output signal which is phase locked to the Sin and Cos inputs of the AD2S99. These inputs are provided by the secondary windings of a resolver. The synthesized reference eliminates the need for preset phase shift circuits and allows synchronous demodulation schemes such as type II tracking converters to be implemented without additional calibration of the total system.

By providing a Synchronous Reference output, the AD2S99 eliminates the temperature dependent phase shifts found with inductive transducers, and their resultant errors.

The AD2S99 requires only one external resistor for operation. The AD2S99 is manufactured on a LC^2MOS process that combines high density, low power CMOS logic with bipolar linear circuitry.

PRODUCT HIGHLIGHTS

Dynamic Phase Compensation

The AD2S99 dynamically compensates for any phase variation in the transducer by phase locking the outputs of the transducer to the synthesized reference output of the AD2S99.

Programmable Frequency

The oscillator frequency is easily programmed to 2 kHz, 5 kHz, 10 kHz or 20 kHz by using the frequency select pins.

Loss of Signal Pin

The "LOS" output indicates a signal failure if both the sensor outputs feeding back to the AD2S99 are lost.

Wide Power Supply Range

The AD2S99 operates over the ±5 V to ±15 V power supply range.

This is a preliminary data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

SPECIFICATIONS (V_S = ±4.75 V to ±15.75 V @ –40°C to +85°C unless otherwise noted)

NOTES

[1]Frequency select pins SEL1 and SEL2 must be connected to appropriate voltage levels before power is applied.

Specifications subject to change without notice.

RECOMMENDED OPERATING CONDITIONS

Power Supply Voltage (V_{DD} to V_{SS}) ..... ±4.75 V to ±15.75 V
Analog Input Voltage (SIN and COS) ..... 2 V rms ±10%
Frequency Select (SEL1 and SEL2) ..... V_{SS} to AGND
Operating Temperature Range ..... –40°C to +85°C

ABSOLUTE MAXIMUM RATINGS*

V_{DD} ..... +16.5 V
V_{SS} ..... –16.5 V
Operating Temperature ..... –40°C to +85°C
Storage Temperature ..... –65°C to +150°C
Analog Input Voltages (SIN and COS) ..... V_{SS} – 0.3 V
..... to V_{DD} + 0.3 V
Frequency Select (SEL1, SEL2) ..... V_{SS} – 0.4 V
..... to AGND + 0.4 V

*Stresses above those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. This is a stress rating only and functional operation of the device at these or any other conditions above those indicated in the operational section of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.

ORDERING GUIDE

Model	Temperature Range	Package Option*
AD2S99?P	–40°C to +85°C	P-20A

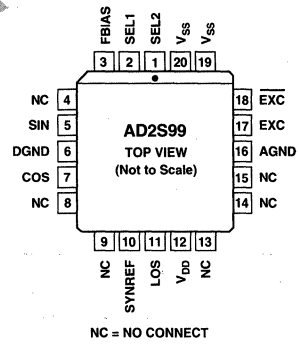
*For outline information see Package Information section.

PIN DESIGNATIONS

Pin No.	Mnemonic	Description
1	SEL2	Frequency Select 2
2	SEL1	Frequency Select 1
3	FBIAS	External Freq. Adjust Pin
5	SIN	Resolver Output SIN
6*	DGND	Digital Ground
7	COS	Resolver Output COS
10	SYNREF	Synthesized Reference Output
11	LOS	Indicates When Both the SIN and COS Are Below the Threshold.
12	V_{DD}	Positive Power Supply
16*	AGND	Analog Ground
17	EXC	Resolver Reference (Plus)
18	$\overline{EXC}$	Resolver Reference (Minus)
19*	V_{SS}	Negative Power Supply
20*	V_{SS}	Negative Power Supply

*Note: Pins 6 and 16 must be connected together and Pins 19 and 20 must be connected together.

PIN CONFIGURATION



CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the AD2S99 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

ANALOG DEVICES

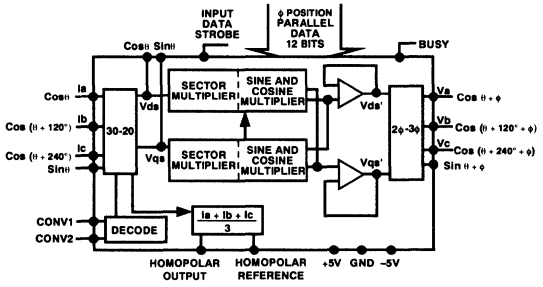
AC Vector Processor

AD2S100

FEATURES
Complete Vector Coordinate Transformation on Silicon
Mixed Signal Data Acquisition
Three-Phase 120° and Orthogonal 90° Signal Transformation
Three-Phase Balance Diagnostic—Homopolar Output

APPLICATIONS
AC Induction and DC Permanent Magnet Motor Control
HVAC, Pump, Fan Control
Material Handling
Robotics
Spindle Drives
Gyroscopes
Dryers
Washing Machines
Electric Cars
Actuators
Three-Phase Power Measurement
Digital-to-Resolver & Synchro Conversion

FUNCTIONAL BLOCK DIAGRAM



GENERAL DESCRIPTION

The AD2S100 performs the vector rotation of three phase 120 degree or two-phase 90 degree sine and cosine signals by transferring these inputs into a new reference frame which is controlled by the digital input angle ϕ. Two transforms are included in the AD2S100. The first is the Clarke transform which computes the sine and cosine orthogonal components of a three phase input. These signals represent real and imaginary components which then form the input to the Park transform. The Park transform relates the angle of the input signals to a reference frame controlled by the digital input port. The digital input is a 12-bit parallel binary representation.

If the input current signals are represented by Vds and Vqs, respectively, where Vds and Vqs are the real and imaginary components, then the transformation can be described as follows:

$$Vds' = Vds \cos\phi - Vqs \sin\phi$$
$$Vqs' = Vds \sin\phi + Vqs \cos\phi$$

Where Vds' and Vqs' are the output of the Park transform and $\sin\phi$, and $\cos\phi$ are the values internally derived by the AD2S100 from the binary digital data.

The input section of the device can be configured to accept either three-phase inputs, two-phase inputs of a three-phase system, or two 90 degree input signals. The homopolar output detects the imbalance of a three-phase input only. Under normal conditions, this output will be zero.

The digital input section will accept a resolution of up to 12 bits (AD2S100). An input data strobe signal is required to synchronize the position data and load this information into the device counters. A busy output is provided to identify the conversion status of the AD2S100. The busy period represents the conversion time of the vector rotation.

Two analog output formats are available. A two-phase rotated output facilitates multiple rotation blocks. Three phase format signals are available for use with a PWM inverter.

PRODUCT HIGHLIGHTS

Hardware Peripheral for Standard Microcontrollers and DSP Systems
The AD2S100 removes the time consuming cartesian transformations from digital processors and benchmarks a speed improvement of 30:1 on standard 20 MHz processors. AD2S100 transformation time = 2 μs (typ).

Field Orientated Control of AC and DC Brushless Motors
The AD2S100 accommodates all the necessary functions to provide a hardware solution for ac vector control of induction motors and dc brushless motors.

Three-Phase Imbalance Detection
The AD2S100 can be used to sense overcurrent situations or imbalances in a three-phase system via the homopolar output.

Resolver to Digital Converter Interface
The AD2S100 provides general purpose interface for position sensors used in the application of dc brushless and ac induction motor control.

NOTES
[1]Angular accuracy includes offsets and gain errors. Stationary digital input and maximum analog frequency inputs.
[2]Included in the angular error is an allowance for the additional error caused by the phase delay as a function of the input frequency. For example if f_{INPUT} = 600 Hz, the contribution to the error due to phase delay in 650 ns × f_{INPUT} × 60 × 360 = 8.4 arc minutes.
[3]Output subject to input voltage and gain.

Specifications in **boldface** are production tested.
Specifications subject to change without notice.

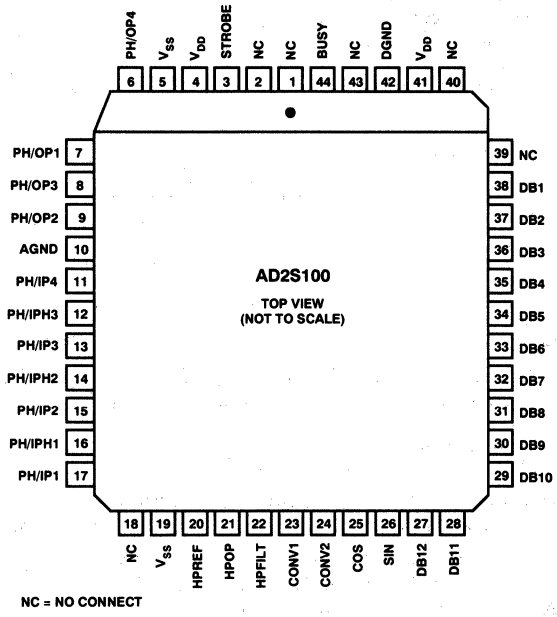
NOTES

Signal Inputs PH/IP and PH/IPH on Pin Nos. 11 through 17.

1. 90° orthogonal signals = Sin θ, Cos θ (Resolver) = PH/IP4 and PH/IP1.
2. Three phase, 120°, three wire signals
   = Cos θ, Cos (θ + 120°), Cos (θ + 240°).
   = PH/IP1, PH/IP2, PH/IP3
   High Level = PH/IPH1, PH/IPH2, PH/IPH3.
3. Three Phase, 120°, two wire signals = Cos (θ + 120°), Cos (θ + 240°) = PH/IP2, PH/IP3.

In all cases where any of the input Pins 11 through 17 are not used, they must be left unconnected.

PIN CONFIGURATION



THEORY OF OPERATION

A fundamental requirement for high quality induction motor drives is that the magnitude and position of the rotating air-gap rotor flux be known. This is normally carried out by measuring the rotor position via a position sensor and establishing a rotor reference frame that can be related to stator current coordinates.

To generate a flux component in the rotor, stator current is applied. A build-up of rotor flux is concluded which must be maintained by controlling the stator current, i_{ds}, parallel to the rotor flux. The rotor flux current component is the magnetizing current, i_{mr}.

Torque is generated by applying a current component which is perpendicular to the magnetizing current. This current is normally called the torque generating current, i_{qs}.

To orient and control both the torque and flux stator current vectors a coordinate transformation is carried out to establish a new reference frame related to the rotor. This complex calculation is carried out by the AD2S100 vector processor.

To expand upon the vector operator a description of a single vector rotation is of assistance. If it is considered that the moduli of a vector is OP and that through the movement of rotor position by ϕ, we require the new position of this vector it can be deduced as follows:

Let original vector OP = A (Cos θ + jSIN θ) where *A* is a constant;

so if, $OQ = OP\ e^{j\phi}$ (1)

and: $e^{j\phi} = \text{Cos}\ \phi + j\text{Sin}\ \phi$

$$OQ = A\ (Cos\ (\theta + \phi) + j\ Sin\ (\theta + \phi))$$
$$= A\ [Cos\ \theta\ Cos\ \phi - Sin\ \theta\ Sin\ \phi + jSin\ \theta\ Cos\ \phi + jCos\ \theta\ Sin\ \phi]$$
$$= A\ [(Cos\ \theta + jSin\ \theta)\ (Cos\ \phi + jSin\ \phi)] \quad (2)$$

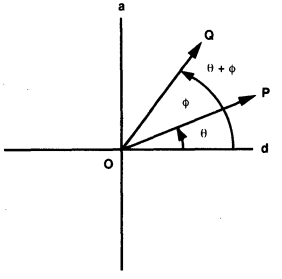


Figure 1. Vector Rotation in Polar Coordinate

The complex stator current vector can be represented as $i_s = i_{as} + ai_{bs} + a^2 i_{cs}$ where $a = e^{\frac{j2\pi}{3}}$ and $a^2 = e^{\frac{j4\pi}{3}}$. This can be replaced by rectangular coordinates as

$$i_s = i_{ds} + ji_{qs} \quad (3)$$

In this equation i_{ds} and i_{qs} represent the equivalent of a two-phase stator winding which establishes the same magnitude of MMF in a three-phase system. These inputs can be seen after the three-phase to two-phase transformation in the AD2S100 block diagram. Equation (3) therefore represents a three-phase to two-phase conversion.

To relate these stator current to the moving reference frame the rotor currents assume the same rectangular coordinates, but are now rotated by the operator $e^{j\phi}$, where $e^{j\phi} = \text{Cos}\ \phi + j\text{Sin}\ \phi$.

Here the term vector rotator comes into play where the stator current vector can be represented in rotor-based coordinates or visa versa.

The AD2S100 uses $e^{j\phi}$ as the core operator. Here ϕ represents the digital position angle which rotates as the rotor moves. In terms of the mathematical function, it rotates the orthogonal i_{ds} and i_{qs} components as follows:

$$i_{ds}' + ji_{qs}' = (I_{ds} + jI_{qs})\ e^{j\phi}$$

where i_{ds}', i_{qs}' = stator currents in the rotor reference frame. And

$$e^{j\phi} = Cos\ \phi + jSin\ \phi$$

$$= (I_{ds} + jI_{qs})(Cos\ \phi + jSin\ \phi)$$

The output from the AD2S100 takes the form of:

$$i_{ds}' = I_{ds}\ Cos\ \phi - I_{qs}\ Sin\ \phi$$
$$i_{qs}' = I_{ds}\ Sin\ \phi + I_{qs}\ Cos\ \phi$$

The matrix equation is:

$$\begin{bmatrix} i_{ds}' \\ i_{qs}' \end{bmatrix} = \begin{bmatrix} Cos\ \phi & -Sin\ \phi \\ Sin\ \phi & Cos\ \phi \end{bmatrix} \begin{bmatrix} I_{ds} \\ I_{qs} \end{bmatrix}$$

and it is shown in Figure 2.

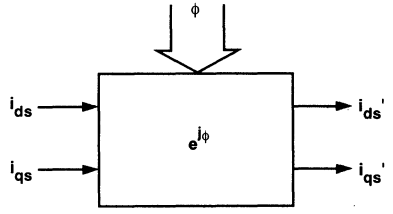

Figure 2. AD2S100 Vector Rotation Operation

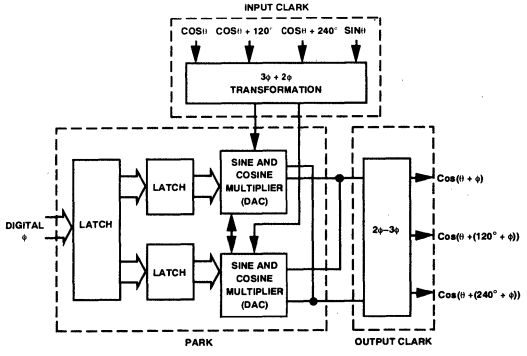

Figure 3. Converter Operation Diagram

16

CONVERTER OPERATION

The architecture of the AD2S100 is illustrated in Figure 3. The AD2S100 is configured in the forward transformation which rotates the rotor frame coordinates to the stator frame.

Forward Rotation

In this configuration the 3ϕ–2ϕ Clark is bypassed, and inputs are fed directly into the quadrature (PH/IP4) and direct (PH/IP1) inputs to the Park transform, $e^{i\phi}$, where ϕ is defined by the AD2S100's digital input. Position data, ϕ, is loaded into the input latch on the positive edge of the strobe pulse. (For detail on the timing, please refer to the "timing diagram.") The negative edge of the strobe signifies that conversion has commenced. A busy pulse is subsequently produced as data is passed from the input latches to the Sin and Cos multipliers. During the loading of the multiplier, the busy pulse remains high to ensure simultaneous setting of ϕ in both the Sin and Cos registers.

The negative edge of the busy pulse signifies that the multipliers are set up and the orthogonal analog inputs are multiplied real time. The resultant two outputs are accessed via the PH/OP1 (Pin 7) and PH/OP4 (Pin 6), alternatively they can be directly applied to the output Clark transform. The Clark output is the vector sum of the analog input vector (Cosθ (PH/OP1), Cos (θ + 120°) (PH/OP2), Cos (θ + 240°) (PH/OP3) and the digital input vector ϕ.

For other configurations, please refer to "Forward and Reverse Transformation."

CONNECTING THE CONVERTER

Power Supply Connection

The power supply voltages connected to V_{DD} and V_{SS} pins should be +5 V dc and −5 V dc and must not be reversed. Pin 4 (V_{DD}) and Pin 41 (V_{DD}) should both be connected to +5 V; similarly, Pin 5 (V_{SS}) and Pin 19 (V_{SS}) should both be connected to −5 V dc.

It is recommended that decoupling capacitors, 100 nF (ceramic) and 10 μF (tantalum) or other high quality capacitors, are connected in parallel between the power line V_{DD}, V_{SS} and AGND adjacent to the converter. Separate decoupling capacitors should be used for each converter. The connections are shown in Figure 4.

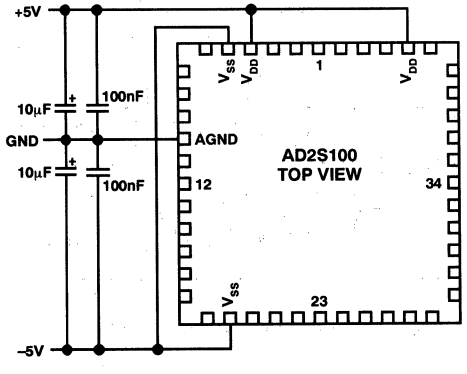

Figure 4. AD2S100 Power Supply Connection

ANALOG SIGNAL INPUT AND OUTPUT CONNECTIONS

Input Analog Signals

All analog signal inputs to AD2S100 are voltages. There are two different voltage levels of three-phase (0°, 120°, 240°) signal inputs. One is the nominal level, which is ±2.8 V dc or 2 V rms and the corresponding input pins are PH/IP1 (Pin 17), PH/IP2 (Pin 15), PH/IP3 (Pin 13) and PH/IP4 (Pin 11).

The high level inputs can accommodate voltages from nominal up to a maximum of $\pm V_{DD}/V_{SS}$. The corresponding input pins are PH/IPH1 (Pin 16), PH/IPH2 (Pin 14) and PH/IPH3 (Pin 12). The homopolar output can only be used in the three-phase connection mode.

The converter can accept both two-phase format and three-phase format input signals. For the two-phase format input, the two inputs must be orthogonal to each other. For the three-phase format input, there is the choice of using all three inputs or using two of the three inputs. In the latter case, the third input signal will be generated internally by using the information of other two inputs. The high level input mode, however, can only be selected with three-phase/three-input format. All these different conversion modes, including nominal/high input level and two/three-phase input format can be selected using two select pins (Pin 23, Pin 24). The functions are summarized in Table I.

Table I. Conversion Mode Selection

Mode	Description	CONV1 (Pin 23)	CONV2 (Pin 24)
MODE1	2-Phase Orthogonal with 2 Inputs Nominal Input Level	NC	DGND
MODE2	3-Phase (0°, 120°, 240°) with 3 Inputs Nominal/High Input Level*	DGND	V_{DD}
MODE3	3-Phase (0°, 120°, 240°) with 2 Inputs Nominal Input Level	V_{DD}	V_{DD}

*The high level input mode can only be selected with MODE2.

MODE1: 2-Phase/2 Inputs with Nominal Input Level
In this mode, PH/IP1 and PH/IP4 are the inputs and the Pins 12 through 16 must be left unconnected.

MODE2: 3-Phase/3 Inputs with Nominal/High Input Level
In this mode, either nominal or high level inputs can be used. For nominal level input operation, PH/IP1, PH/IP2 and PH/IP3 are the inputs, and there should be no connections to PH/IPH1, PH/IPH2 and PH/IPH3; similarly, for high level input operation, the PH/IPH1, PH/IPH2 and PH/IPH3 are the inputs, and there should be no connections to PH/IP1, PH/IP2 and PH/IP3. In both cases, the PH/IP4 should be left unconnected. For high level signal input operation, select MODE2 only.

MODE3: 3-Phase/2 Inputs with Nominal Input Level
In this mode, PH/IP2 and PH/IP3 are the inputs and the third signal will be generated internally by using the information of other two inputs. It is recommended that PH/IP1, PH/IPH1, PH/IPH2, PH/IP4 and PH/IPH3 should be left unconnected.

Output Analog Signals
There are three forms of analog output from the AD2S100.

Sin/Cos orthogonal output signals are derived from the Clark/three-to-two-phase conversion before the Park angle rotation. These signals are available on Pin 25 (Cos θ) and Pin 26 (Sin θ), and occur before Park angle rotation.

Three-Phase Output Signals
(Cos (θ + ϕ), Cos (ϕ + θ + 120°), Cos (ϕ + θ + 240°)), where ϕ represents digital input angle. These signals are available on Pin 7 (PH/OP1), Pin 9 (PH/OP2) and Pin 8 (PH/OP3), respectively.

Two-Phase (Sin (θ + ϕ), Cos (θ + ϕ)) Signals
These represent the output of the coordinate transformation. These signals are available on Pin 6 (PH/OP4, Sin (θ + ϕ)) and Pin 7 (PH/OP1, Cos (θ + ϕ)).

HOMOPOLAR OUTPUT

Homopolar Reference
In a three-phase ac system, the sum of the three inputs to the converter can be used to indicate whether or not the phases are balanced.

If V_{SUM} = PH/IP1 + PH/IP2 + PH/IP3 (or PH/IPH1 + PH/IPH2 +PH/IPH3) this can be rewritten as V_{SUM} = [Cosθ,+ Cos (θ + 120°) + Cos (θ + 240°)] = 0. Any imbalances in the line will cause the sum $V_{SUM} \neq 0$. The AD2S100 homopolar output (HPOP) goes high when $V_{SUM} > 3 \times V_{ts}$. The voltage level at which the HPOP indicates an imbalance is determined by the HPREF threshold, V_{ts}. This is set internally at ±0.5 V dc (±0.1 V dc). The HPOP goes high when

$$V_{ts} < \frac{(Cos\theta + Cos\ (\theta + 120°) + Cos\ (\theta + 240°))}{3} \times V$$

where V is the nominal input voltage.

With no external components V_{SUM} must exceed ±1.5 V dc in order for HPOP to indicate an imbalance. The sensitivity of the threshold can be reduced by connecting an external resistor between HPOP and ground as shown in Figure 5, where,

$$V_{ts} = \frac{0.5\ R_{EXT}}{R_{EXT} + 20000}$$

R_{EXT} = Ω
V_{ts} = V dc.

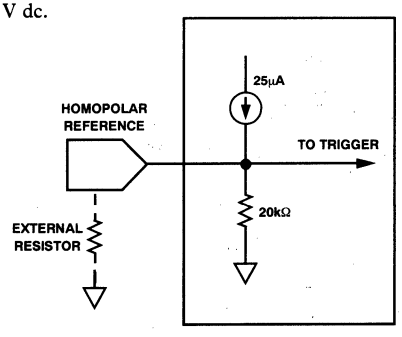

Figure 5. The Equivalent Homopolar Reference Input Circuitry

Example: From the equivalent circuit, it can be seen that the inclusion of a 20 kΩ resistor will reduce V_{ts} to ±0.25 V dc. This corresponds to an imbalance of ±0.75 V dc in the inputs.

Homopolar Filtering
The equation V_{SUM} = Cosθ + Cos (θ + 120°) + Cos (θ + 240°) = 0 denotes an imbalance when $V_{SUM} \neq 0$. There are conditions, however, when an actual imbalance will occur and the conditions as define by V_{SUM} will be valid. For example, if the first phase was open circuit when θ = 90° or 270°, the first phase is valid at 0 V dc. V_{SUM} is valid, therefore, when Cosθ is close to 0. In order to detect an imbalance θ has to move away from 90° or 270°, i.e., when on a balanced line Cos θ ≠ 0.

Line imbalance is detected as a function of HPREF, either set by the user or internally set at ±0.5 V dc. This corresponds to a dead zone when ϕ = 90° or 270° ± 30°, i.e., V_{SUM} = 0, and, therefore, no indicated imbalance. If an external 20 kΩ resistor is added, this halves V_{ts} and reduces the zone to ±15°. Note this example only applies if the first phase is detached.

In order to prevent this false triggering an external capacitor needs to be placed from HPFILT to ground, as shown in Figure 5. This averages out the perceived imbalance over a complete cycle and will prevent the HPOP from alternatively indicating balance and imbalance over θ = 0° to 360°.

For

$$\frac{d\theta}{dt} = 1000\ rpm \quad C_{EXT} = 200\ nF$$

$$\frac{d\theta}{dt} = 100\ rpm \quad C_{EXT} = 2.2\ \mu F$$

Note: The slower the input rotational speed, the larger the time constant required over which to average the HPOP output. Use of the homopolar output at slow rotational speeds becomes impractical with respect to the increased value for C_{EXT}.

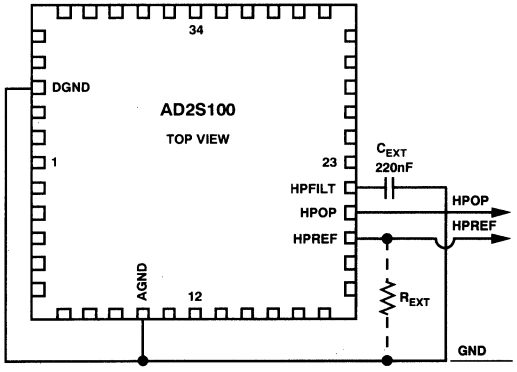

Figure 6. AD2S100 Homopolar Output Connections

16

TIMING DIAGRAMS

Busy Output

The state of converter is indicated by the state of the BUSY output (Pin 44). The BUSY output will go HI at the negative edge of the STROBE input. This is used to synchronize digital input data and load the digital angular rotation information into the device counter. The BUSY output will remain HI for 2 μs, and go LO until the next strobe negative edge occurs.

Strobe Input

The width of the positive STROBE pulse should be at least 100 ns, in order to successfully start the conversion. The maximum frequency of STROBE input is 366 kHz, i.e., there should be at least 2.73 μs from the negative edge of one STROBE pulse to the next rising edge. This is illustrated by the following timing diagram and table.

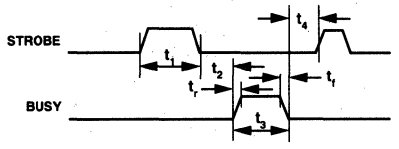

Figure 7. AD2S100 Timing Diagram

Note: Digital data should be stable 25 ns before and after positive strobe edge.

Table II. AD2S100 Timing Table

Parameter	Min	Typ	Max	Condition
t_1	100 ns			STROBE Pulse Width
t_2		30 ns		STROBE ↓ to BUSY ↑
t_3	1.7 μs		2.5 μs	BUSY Pulse Width
t_4		100 ns		BUSY ↓ to STROBE ↑
t_r		20 ns		BUSY Pulse Rise Time with No Load
		150 ns		BUSY Pulse Rise Time with 68 pF Load
t_f		10 ns		BUSY Pulse Fall Time with No Load
		120 ns		BUSY Pulse Fall Time with 68 pF Load

TYPICAL CIRCUIT CONFIGURATION

Figure 8 shows a typical circuit configuration for the AD2S100 in a three phase, nominal level input mode (MODE2).

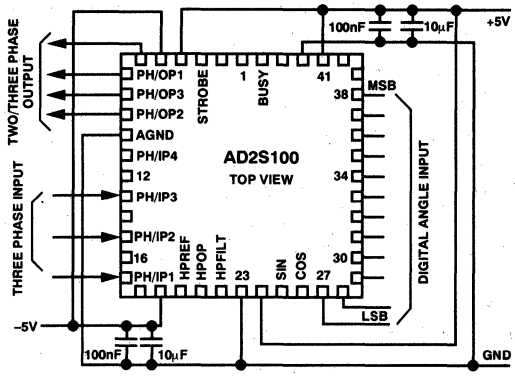

Figure 8. Typical Circuit Configuration

APPLICATIONS

Forward and Reverse Transformation

The AD2S100 can perform both forward and reverse transformations. The section "Theory of Operation" explains how the chip operates with the core operator $e^{+j\phi}$, which performs a forward transformation. The reverse transformation, $e^{-j\phi}$, is not mentioned in the above sections of the data sheet simply to avoid the confusion in the functionality and pinout. However, the reverse transformation is very useful in many different applications, and the AD2S100 can be easily configured in a reverse transformation configuration. Figure 9 shows four different phase input/output connections for AD2S100 reverse transformation operation.

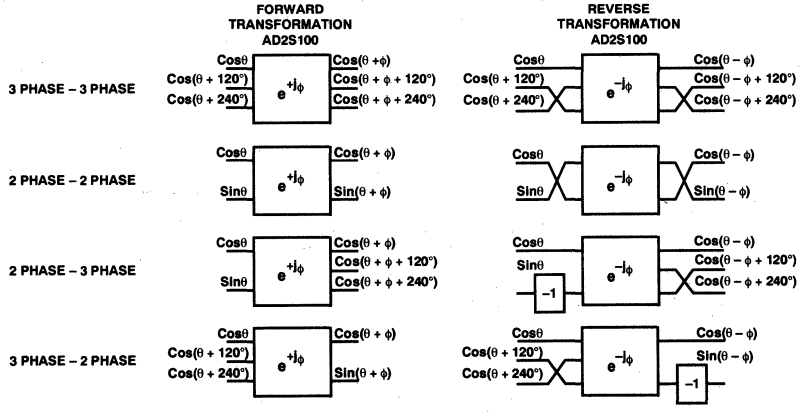

Figure 9. Reverse Transformation Connections

√In Figure 9, "−1" operator performs a 180° phase shift operation. It can be illustrated by a 2-phase-to-3-phase reverse transformation. An example is shown in Figure 10.

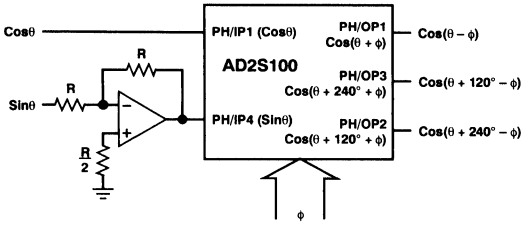

Figure 10. Two-Phase to Three-Phase Reverse Transformation

Field Oriented Control of AC Induction Machine in a Rotor Flux Frame

The architecture shown in Figure 11 identifies a simplified scheme where the AD2S100 permits the DSP computing core to execute the motor control in what is normally termed the rotor reference frame. This reference frame actually operates in synchronism with the rotor of a motor. This has significant benefits regarding motor control efficiency and economics. The calculating power required in the rotor reference frame is significantly reduced because the currents and flux are rotating at the slip frequency. This permits calculations to be carried out in time frames of, 100 μs, or under by a fixed-point DSP. Benchmark timing in this type of architecture can attain floating-point speed processing with a fixed-point processor. Perhaps the largest advantage is in the ease with which the rotor flux position can be obtained. A large amount of computation time is, therefore, removed by the AD2S100 vector processors due to the split architecture shown in Figure 11. Motor control systems employing one DSP to carry out the cartesian to polar transformations required for vector control are, therefore, tasked with additional duties due to the fact that they normally operate in the flux reference frame.

The robustness of the control system can also be increased by carrying out the control in the rotor reference frame. This is achieved through the ability to increase and improve both the algorithm quality in nonlinear calculations attributed to magnetizing inductance and rotor time constant for example. An increase in sampling time can also be concluded with this architecture by avoiding the additional computing associated with number truncation and rounding errors which reduce the signal to noise rejection ratio.

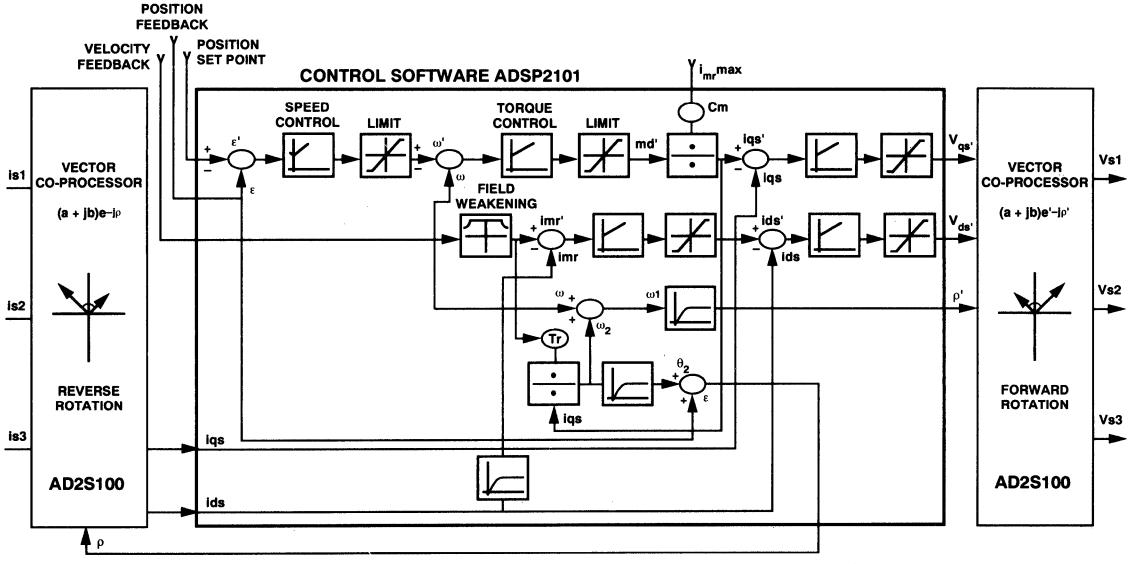

Figure 11. Rotor Reference Frame Architecture

16

SIMPLE SLIP CONTROL

In an adjustable-frequency drive, the control strategy must ensure that motor operation is restricted to low slip frequencies, resulting in stable operation with a high power factor and a high torque per stator ampere. Figure 12 shows the block diagram of simple slip control using the AD2S100. Here, the slip frequency command ω_2 and the current amplitude command are sent to the microprocessor to generate two orthogonal signals, $|I|$ Sin θ and $|I|$ Cos θ here ($\theta = \omega_2$.) With the actual shaft position angle, ϕ, (resolver-to-digital converter) and the orthogonal signals from

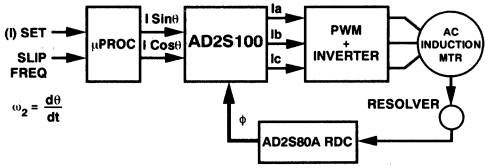

Figure 12. Slip Control of AC Induction Motor with AD2S100

the µP, the AD2S100 generates the inverter frequency and amplitude command into a three-phase format. The three-phase sine wave reference currents are reproduced in the stator phases. For general applications, both the steady-state and dynamic performance of this simple control scheme is satisfactory. For detailed information about this application, please refer to the bibliography at the end of the data sheet.

ADVANCED PMSM SERVO CONTROL

Electronically commutated permanent magnet synchronous motors (PMSM) are used in high performance drives for machine tools and robotics. When a field orientated control scheme is deployed, the resulting brushless drive has all the properties required for servo applications in machine tool fed drives, industrial robots, and spindle drives. These properties include large torque/inertia ratio, a high peak torque capability for fast acceleration and deceleration with high torsional stiffness at standstill.

Figure 13 shows the AD2S100 configured for both forward and reverse transformations. This architecture concludes both flux and torque current components independently. The additional control of Vd (flux component) allows for the implementation of field weakening schemes and maintenance of power factor.

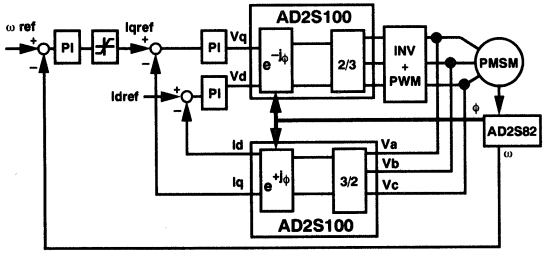

Figure 13. PMSM Servo Control Using AD2S100

For more detailed information, please refer to the application note "Vector Control Using a Single Vector Rotation Semiconductor for Induction and Permanent Magnet Motors."

MOTION CONTROL DSP COPROCESSOR

AC induction motors are superior to dc motors with respect to size/power ratio, weight, rotor inertia, maximum rotating velocity, efficiency and cost for motor ratings greater than 5 HP. However, because of nonlinear and the highly interactive multivariable control structure, ac induction motors have been considered difficult to control in applications demanding variable speed and torque.

Field orientated control theory and practice, under development since 1975, has offered the same level of control enjoyed by traditional dc machines. Practical implementation of these algorithms involves the use of DSP and microprocessor based architectures. The AD2S100 removes the needs for software implementation of the rotor-to-stator and stator-to-rotor transformations in the DSP or µP. The reduction in throughput times from typically 100 µs (µP) and 40 µs (DSP) to 2 µs increases system bandwidths while also allowing additional features to be added to the CPU. The combination of the fixed point ADSP-2101 and the AD2S100, the "advanced motion control engine" shown in Figure 14, enables bandwidths previously attainable only through the use of floating point devices.

For more detailed information on the AD2S100 vector control application and on this advanced motion control engine, please refer to application notes "Vector Control Using a Single Vector Rotation Semiconductor for Induction and Permanent Magnet Motors."

MEASUREMENT OF HARMONICS

Three-phase ac power systems are widely used in power generation, transmission and electric drive. The quality of the electricity supply is affected by harmonics injected into the power main. In inverter fed ac machines, fluxes and currents of various frequencies are produced. Predominantly in ac machines the 5th and 7th harmonics are the most damaging; their reaction with the fundamental flux component produces 6th harmonic torque pulsations. The subsequent pulsating torque output may result in uneven motion of the motor, especially at low speeds.

The AD2S100 can be used to monitor and detect the presence and magnitude of a particular harmonic on a three-phase line. Figure 15 shows the implementation of such a scheme using the AD2S100. Note, the actual line voltages will have to be scaled before applying to the three-phase input of the AD2S100.

Selecting a harmonic is achieved by synchronizing the rotational frequency of the park digital input, ϕ, with the frequency of the fundamental flux component and the integer harmonic selected. The update rate, r, of the counters is determined by:

$$r = 4096 \times \frac{n \times \omega}{2\pi}$$

Here, r = input clock pulse rate (pulses/second);
n = the order of harmonics to be measured;
ω = fundamental angular frequency of the ac signal.

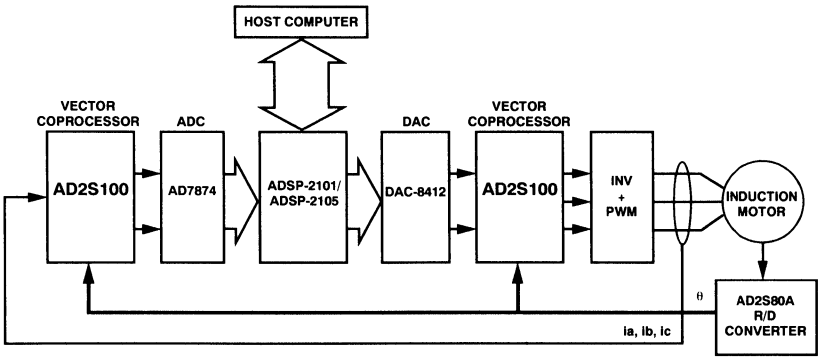

Figure 14. Advanced Motion Control Engine

The magnitude of the n-th harmonic as well as the fundamental component in the power line is represented by the output of the low-pass filter, a_k. In concert with magnitude of the harmonic the AD2S100 homopolar output will indicate whether the three phases are balanced or not. For more details about this application, refer to the related application note listed in the bibliography.

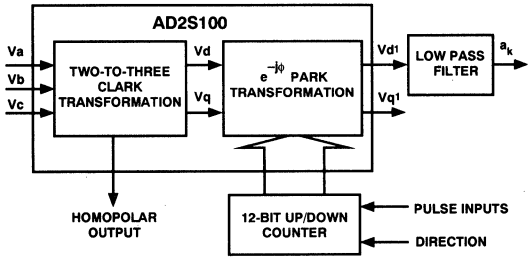

Figure 15. Harmonics Measurement Using AD2S100

MULTIPLE POLE MOTORS

For multi-pole motor applications where a single speed resolver is used, the AD2S100 input has to be configured to match the electrical cycle of the resolver with the phasing of the motor windings. The input to the AD2S100 is the output of a resolver-to-digital converter, e.g., AD2S80A series. The parallel output of the converter needs to be multiplied by 2^{n-1}, where n = the number of pole parts of the motor. In practice this is implemented by shifting the parallel output of the converter left relative to the number of pole pairs.

Figure 16 shows the generic configuration of the AD2S80A with the AD2S100 for a motor with n pole pairs. The MSB of the AD2S100 is connected to MSB-(n-1) bit of the AD2S80A digital output, MSB-1 bit to MSB-(n-2) bit, . . . , LSB bit to LSB bit of AD2S80A, etc.

Figure 17 shows the AD2S80A configured for use with a four pole motor, where n = 2. Using the formula described the MSB is shifted left once.

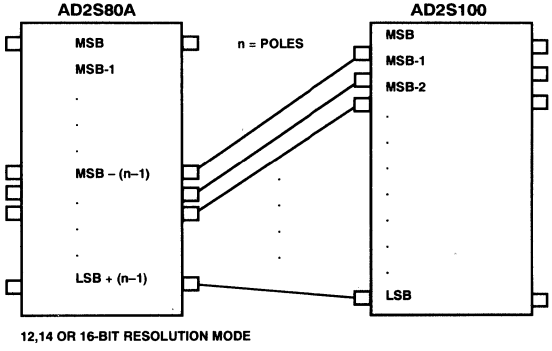

Figure 16. A General Consideration in Connecting R/D Converter and AD2S100 for Multiple Pole Motors

16

DIGITAL-TO-RESOLVER AND SYNCHRO CONVERSION

The AD2S100 can be configured for use as a 12-bit digital-to-resolver (DRC) or synchro converter (DSC). DRCs and DSCs are used to simulate the outputs of a resolver or a synchro. The simulated outputs are represented by the transforms outlined below.

Resolver Outputs

Asinωt.cosϕ
Asinωt.sinϕ

Synchro Outputs

Asinωt.sinϕ
Asinωt.sin (ϕ + 120°)
Asinωt.sin (ϕ + 240°)

where: *Asinωt* = fixed ac reference

ϕ = digital input angle, i.e., shaft position

The waveforms are shown in Figures 18 and 19.

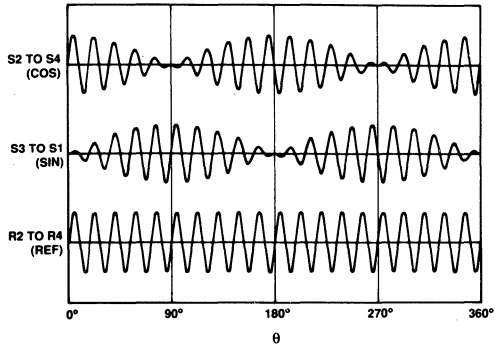

Figure 18. Electrical Representation and Typical Resolver Signals

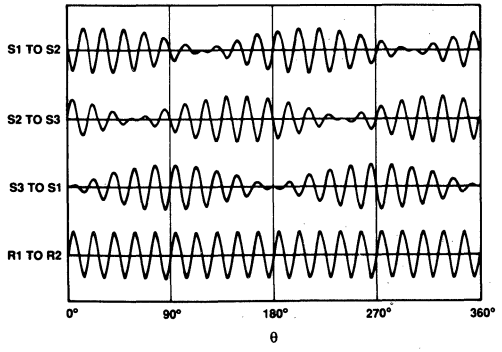

Figure 19. Electrical Representation and Typical Synchro Signals

Configuring the AD2S100 for DRC and DSC operation is done by the following.

DRC—Must Select Mode 1

Inputs	PH/IP4	Pin 11	AGND
	PH/IP1	Pin 17	Reference Asinωt
Outputs	PH/OP1	Pin 7	Asinωt Cosϕ
	PH/OP4	Pin 6	Asinωt Sinϕ

DSC—Must Select Mode 1

Inputs	PH/IP4	Pin 11	Reference Asinωt
	PH/IP1	Pin 17	AGND
Outputs	PH/OP1	Pin 7	−Asinωt Sinϕ
	PH/OP2	Pin 9	−Asinωt Sin (ϕ + 120°)
	PH/OP3	Pin 8	−Asinωt Sin (ϕ + 240°)

NOTES

1. Valid information is only available after the strobe pulse and BUSY go low. For more information on DRCs see the AD2S65/AD2S66 data sheet.
2. To correct for inverse phasing of the DSC outputs the reference should be inverted, or the MSB can be inverted.

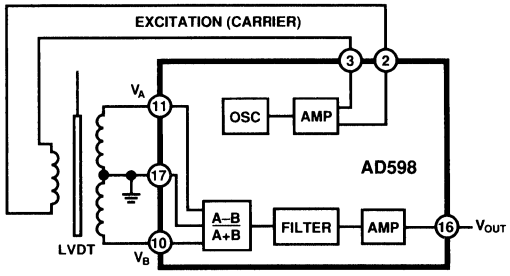
LVDT Signal Conditioner

AD598

FEATURES

Single Chip Solution, Contains Internal Oscillator and Voltage Reference
No Adjustments Required
Insensitive to Transducer Null Voltage
Insensitive to Primary to Secondary Phase Shifts
DC Output Proportional to Position
20 Hz to 20 kHz Frequency Range
Single or Dual Supply Operation
Unipolar or Bipolar Output
Will Operate a Remote LVDT at Up to 300 Feet
Position Output Can Drive Up to 1000 Feet of Cable
Will Also Interface to an RVDT
Outstanding Performance
Linearity: 0.05% of FS max
Output Voltage: ±11 V min
Gain Drift: 50 ppm/°C of FS max
Offset Drift: 50 ppm/°C of FS max

FUNCTIONAL BLOCK DIAGRAM



PRODUCT DESCRIPTION

The AD598 is a complete, monolithic Linear Variable Differential Transformer (LVDT) signal conditioning subsystem. It is used in conjunction with LVDTs to convert transducer mechanical position to a unipolar or bipolar dc voltage with a high degree of accuracy and repeatability. All circuit functions are included on the chip. With the addition of a few external passive components to set frequency and gain, the AD598 converts the raw LVDT secondary output to a scaled dc signal. The device can also be used with RVDT transducers.

The AD598 contains a low distortion sine wave oscillator to drive the LVDT primary. The LVDT secondary output consists of two sine waves that drive the AD598 directly. The AD598 operates upon the two signals, dividing their difference by their sum, producing a scaled unipolar or bipolar dc output.

The AD598 uses a unique ratiometric architecture (patent pending) to eliminate several of the disadvantages associated with traditional approaches to LVDT interfacing. The benefits of this new circuit are: no adjustments are necessary, transformer null voltage and primary to secondary phase shift does not affect system accuracy, temperature stability is improved, and transducer interchangeinterchangeabilityability is improved.

The AD598 is available in two performance grades:

Grade	Temperature Range	Package
AD598JR	0 to +70°C	20-Pin Small Outline (SOIC)
AD598AD	−40°C to +85°C	20-Pin Ceramic DIP

It is also available processed to MIL-STD-883B, for the military range of −55°C to +125°C.

PRODUCT HIGHLIGHTS

1. The AD598 offers a monolithic solution to LVDT and RVDT signal conditioning problems; few extra passive components are required to complete the conversion from mechanical position to dc voltage and no adjustments are required.
2. The AD598 can be used with many different types of LVDTs because the circuit accommodates a wide range of input and output voltages and frequencies; the AD598 can drive an LVDT primary with up to 24 V rms and accept secondary input levels as low as 100 mV rms.
3. The 20 Hz to 20 kHz LVDT excitation frequency is determined by a single external capacitor. The AD598 input signal need not be synchronous with the LVDT primary drive. This means that an external primary excitation, such as the 400 Hz power mains in aircraft, can be used.
4. The AD598 uses a ratiometric decoding scheme such that primary to secondary phase shifts and transducer null voltage have absolutely no effect on overall circuit performance.
5. Multiple LVDTs can be driven by a single AD598, either in series or parallel as long as power dissipation limits are not exceeded. The excitation output is thermally protected.
6. The AD598 may be used in telemetry applications or in hostile environments where the interface electronics may be remote from the LVDT. The AD598 can drive an LVDT at the end of 300 feet of cable, since the circuit is not affected by phase shifts or absolute signal magnitudes. The position output can drive as much as 1000 feet of cable.
7. The AD598 may be used as a loop integrator in the design of simple electromechanical servo loops.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

AD598—SPECIFICATIONS (typical @ +25°C and ±15 V dc, C1 = 0.015 μF, R2 = 80 kΩ, R_L = 2 kΩ, unless otherwise noted. See Figure 7.)

NOTES

[1]V_A and V_B represent the Mean Average Deviation (MAD) of the detected sine waves. Note that for this Transfer Function to linearly represent positive displacement, the sum of V_A and V_B of the LVDT must remain constant with stroke length. See "Theory of Operation." Also see Figures 7 and 12 for R2.

[2]From T_{min} to T_{max} the overall error due to the AD598 alone is determined by combining gain error, gain drift and offset drift. For example, the worst case overall error for the AD598AD from T_{min} to T_{max} is calculated as follows: overall error = gain error at +25°C (±1% full scale) + gain drift from −40°C to +25°C (50 ppm/°C of FS × +65°C) + offset drift from −40°C to +25°C (50 ppm/°C of FS× 65°C) = ±1.65% of full scale. Note that 1000 ppm of full scale equals 0.1% of full scale. Full scale is defined as the voltage difference between the maximum positive and maximum negative output.

[3]Nonlinearity of the AD598 only, in units of ppm of full scale. Nonlinearity is defined as the maximum measured deviation of the AD598 output voltage from a straight line. The straight line is determined by connecting the maximum produced full-scale negative voltage with the maximum produced full-scale positive voltage.

[4]See Transfer Function.

[5]This offset refers to the $(V_A-V_B)/(V_A+V_B)$ input spanning a full-scale range of ±1. [For $(V_A-V_B)/(V_A+V_B)$ to equal +1, V_B must equal zero volts; and correspondingly for $(V_A-V_B)/(V_A+V_B)$ to equal −1, V_A must equal zero volts. Note that offset errors do not allow accurate use of zero magnitude inputs; practical inputs are limited to 100 mV rms.] The ±1 span is a convenient reference point to define offset referred to input. For example, with this input span a value of R2 = 20 kΩ would give V_{OUT} span a value of ±10 volts. Caution, most LVDTs will typically exercise less of the $(V_A-V_B)/(V_A+V_B)$ input span and thus require a larger value of R2 to produce the ±10 V output span. In this case the offset is correspondingly magnified when referred to the output voltage. For example, a Schaevitz E100 LVDT requires 80.2 kΩ for R2 to produce a ±10.69 V output and $(V_A-V_B)/(V_A+V_B)$ equals 0.27. This ratio may be determined from the graph shown in Figure 18, $(V_A-V_B)/(V_A+V_B)$ = (1.71 V rms−0.99 V rms)/(1.71 V rms+0.99 V rms). The maximum offset value referred to the ±10.69 V output may be determined by multiplying the maximum value shown in the data sheet (±1% of FS by 1/0.27 which equals ±3.7% maximum. Similarly, to determine the maximum values of offset drift, offset CMRR and offset PSRR when referred to the ±10.69 V output, these data sheet values should also be multiplied by (1/0.27). For this example, for the AD598AD the maximum values of offset drift, PSRR offset and CMRR offset would be: 185 ppm/°C of FS; 741 ppm/V and 741 ppm/V respectively when referred to the ±10.69 V output.

[6]For example, if the excitation to the primary changes by 1 dB, the gain of the system will change by typically 100 ppm.

[7]Output ripple is a function of the AD598 bandwidth determined by C2, C3 and C4. See Figures 16 and 17.

[8]R1 is shown in Figures 7 and 12.

[9]Excitation voltage drift is not an important specification because of the ratiometric operation of the AD598.

THEORY OF OPERATION

A block diagram of the AD598 along with an LVDT (Linear Variable Differential Transformer) connected to its input is shown in Figure 5. The LVDT is an electromechanical transducer whose input is the mechanical displacement of a core and whose output is a pair of ac voltages proportional to core position. The transducer consists of a primary winding energized by an external sine wave reference source, two secondary windings connected in series, and the moveable core to couple flux between the primary and secondary windings.

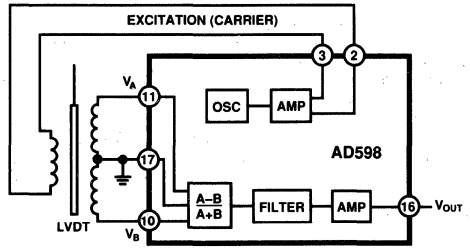

Figure 5. AD598 Functional Block Diagram

The AD598 energizes the LVDT primary, senses the LVDT secondary output voltages and produces a dc output voltage proportional to core position. The AD598 consists of a sine wave oscillator and power amplifier to drive the primary, a decoder which determines the ratio of the difference between the LVDT secondary voltages divided by their sum, a filter and an output amplifier.

The oscillator comprises a multivibrator which produces a triwave output. The triwave drives a sine shaper, which produces a low distortion sine wave whose frequency is determined by a single capacitor. Output frequency can range from 20 Hz to 20 kHz and amplitude from 2 V rms to 24 V rms. Total harmonic distortion is typically −50 dB.

The output from the LVDT secondaries consists of a pair of sine waves whose amplitude difference, $(V_A–V_B)$, is proportional to core position. Previous LVDT conditioners synchronously detect this amplitude difference and convert its absolute value to a voltage proportional to position. This technique uses the primary excitation voltage as a phase reference to determine the polarity of the output voltage. There are a number of problems associated with this technique such as (1) producing a constant amplitude, constant frequency excitation signal, (2) compensating for LVDT primary to secondary phase shifts, and (3) compensating for these shifts as a function of temperature and frequency.

The AD598 eliminates all of these problems. The AD598 does not require a constant amplitude because it works on the ratio of the difference and sum of the LVDT output signals. A constant frequency signal is not necessary because the inputs are rectified and only the sine wave carrier magnitude is processed. There is no sensitivity to phase shift between the primary excitation and the LVDT outputs because synchronous detection is not employed. The ratiometric principle upon which the AD598 operates requires that the sum of the LVDT secondary voltages remains constant with LVDT stroke length. Although LVDT manufacturers generally do not specify the relationship between V_A+V_B and stroke length, it is recognized that some LVDTs do not meet this requirement. In these cases a nonlinearity will result. However, the majority of available LVDTs do in fact meet these requirements.

The AD598 utilizes a special decoder circuit. Referring to the block diagram and Figure 6 below, an implicit analog computing loop is employed. After rectification, the A and B signals are multiplied by complementary duty cycle signals, d and (1–d) respectively. The difference of these processed signals is integrated and sampled by a comparator. It is the output of this comparator that defines the original duty cycle, d, which is fed back to the multipliers.

As shown in Figure 2, the input to the integrator is [(A+B)d]-B. Since the integrator input is forced to 0, the duty cycle $d = B/(A+B)$.

The output comparator which produces $d = B/(A+B)$ also controls an output amplifier driven by a reference current. Duty cycle signals d and (1−d) perform separate modulations on the reference current as shown in Figure 6, which are summed. The summed current, which is the output current, is $I_{REF} \times (1-2d)$. Since $d \doteq B/(A+B)$, by substitution the output current equals $I_{REF} \times (A-B)/(A+B)$. This output current is then filtered and converted to a voltage since it is forced to flow through the scaling resistor R2 such that:

$$V_{OUT} = I_{REF} \times (A-B)/(A+B) \times R2$$

ANALOG DEVICES

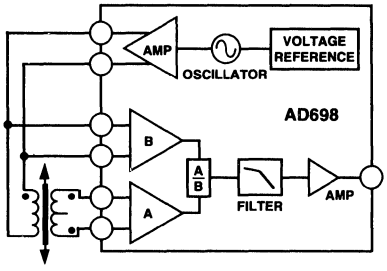
Universal LVDT Signal Conditioner

AD698

FEATURES

Single Chip Solution, Contains Internal Oscillator and Voltage Reference
No Adjustments Required
Interfaces to Half-Bridge LVDT, 4-Wire LVDT
DC Output Proportional to Position
20 Hz to 20 kHz Frequency Range
Unipolar or Bipolar Output
Will Also Implement AC Bridge
Outstanding Performance
Linearity: 0.05%
Output Voltage: ±11 V
Gain Drift: 20 ppm/°C (typ)
Offset Drift: 5 ppm/°C (typ)

FUNCTIONAL BLOCK DIAGRAM



PRODUCT DESCRIPTION

The AD698 is a complete, monolithic Linear Variable Differential Transformer (LVDT) signal conditioning subsystem. It is used in conjunction with LVDTs to convert transducer mechanical position to a unipolar or bipolar dc voltage with a high degree of accuracy and repeatability. All circuit functions are included on the chip. With the addition of a few external passive components to set frequency and gain, the AD698 converts the raw LVDT output to a scaled dc signal. The device will operate with half-bridge LVDTs, LVDTs connected in the series opposed configuration, (4-wire), RVDTs.

The AD698 contains a low distortion sine wave oscillator to drive the LVDT primary. Two synchronous demodulation channels of the AD698 are used to detect primary and secondary amplitude. The part divides the output of the secondary by the amplitude of the primary and multiplies by a scale factor. This eliminates scale factor errors due to drift in the amplitude of the primary drive, improving temperature performance and stability.

The AD698 uses a unique ratiometric architecture to eliminate several of the disadvantages associated with traditional approaches to LVDT interfacing. The benefits of this new circuit are: no adjustments are necessary; temperature stability is improved; and transducer interchangeability is improved.

The AD698 is available in two performance grades:

Grade	Temperature Range	Package
AD698AP	−40°C to +85°C	28-Pin PLCC
AD698SQ	−55°C to +125°C	24-Pin Cerdip

PRODUCT HIGHLIGHTS

1. The AD698 offers a single chip solution to LVDT signal conditioning problems. All active circuits are on the monolithic chip with only passive components required to complete the conversion from mechanical position to dc voltage.
2. The AD698 can be used with many different types of position sensors. The circuit is optimized for use with any LVDT, including half-bridge and series opposed, (4 wire) configurations. The AD698 accommodates a wide range of input and output voltages and frequencies.
3. The 20 Hz to 20 kHz excitation frequency is determined by a single external capacitor. The AD698 provides up to 24 volts rms to differentially drive the LVDT primary, and the AD698 meets its specifications with secondary input levels as low as 100 millivolts rms.
4. Change in oscillator amplitude with temperature will not affect overall circuit performance. The AD698 computes the ratio of the secondary voltage to the primary voltage to determine position and direction. No adjustments are required.
5. Multiple LVDTs can be driven by a single AD698 either in series or parallel as long as power dissipation limits are not exceeded. The excitation output is thermally protected.
6. The AD698 may be used as a loop integrator in the design of simple electromechanical servo loops.
7. The sum of the secondaries' voltages do not need to be constant.

NOTES
[1]A and B represent the Mean Average Deviation (MAD) of the detected sine waves V_A and V_B. The polarity of V_{OUT} is affected by the sign of the A comparator, i.e., multiply $V_{OUT} \times +1$ for $A_{COMP+} > A_{COMP-}$, and $V_{OUT} \times -1$ for $A_{COMP-} > A_{COMP+}$.
[2]Nonlinearity of the AD698 only in units of ppm of full scale. Nonlinearity is defined as the maximum measured deviation of the AD698 output voltage from a straight line. The straight line is determined by connecting the maximum produced full-scale negative voltage with the maximum produced full-scale positive voltage.
[3]See Transfer Function.
[4]For example, if the excitation to the primary changes by 1 dB, the gain of the system will change by typically 100 ppm.
[5]Output ripple is a function of the AD698 bandwidth determined by C1 and C2. A 1000 pF capacitor should be in parallel with R2 to reduce the output ripple. See Figures 7 and 13.
[6]R1 is shown in Figures 7 and 13.
[7]Excitation voltage drift is not an important specification because of the ratiometric operation of the AD698.
[8]From T_{MIN} to T_{MAX} the overall error due to the AD698 alone is determined by combining gain error, gain drift and offset drift. For example, the typical overall error for the AD698AP from T_{MIN} to T_{MAX} is calculated as follows: Overall Error = Gain Error at 25°C (±0.2% Full Scale) + Gain Drift from −40°C to 25°C (20 ppm/°C × 65°C) + Offset Drift from −40°C to 25°C (5 ppm/°C × 65°C) = ±0.36% of full scale. Note that 1000 ppm of full scale equals 0.1% of full scale.

Specifications subject to change without notice.
Specifications shown in boldface are tested on all production units at final electrical test. Results from those tested are used to calculate outgoing quality levels. All min and max specifications are guaranteed, although only those shown in **boldface** are tested on all production units.

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the AD698 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

THEORY OF OPERATION

A block diagram of the AD698 along with an LVDT (linear variable differential transformer) connected to its input is shown in Figure 5 below. The LVDT is an electromechanical transducer—its input is the mechanical displacement of a core, and its output is an ac voltage proportional to core position. Two popular types of LVDTs are the half-bridge type and the series opposed or four-wire LVDT. In both types the moveable core couples flux between the windings. The series-opposed connected LVDT transducer consists of a primary winding energized by an external sine wave reference source and two secondary windings connected in the series opposed configuration. The output voltage across the series secondary increases as the core is moved from the center. The direction of movement is detected by measuring the phase of the output. Half-bridge LVDTs have a single coil with a center tap and work like an autotransformer. The excitation voltage is applied across the coil; the voltage at the center tap is proportional to position. The device behaves very similar to a resistive voltage divider.

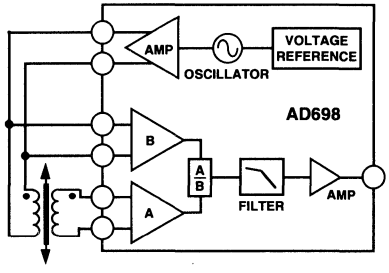

Figure 5. Functional Block Diagram

The AD698 energizes the LVDT coil, senses the LVDT output voltages and produces a dc output voltage proportional to core position. The AD698 has a sine wave oscillator and power amplifier to drive the LVDT. Two synchronous demodulation stages are available for decoding the primary and secondary voltages. A decoder determines the ratio of the output signal voltage to the input drive voltage, (A/B). A filter stage and output amplifier are used to scale the resulting output.

The oscillator comprises a multivibrator which produces a triwave output. The triwave drives a sine shaper which produces a low distortion sine wave. Frequency and amplitude are determined by a single resistor and capacitor. Output frequency can range from 20 Hz to 20 kHz and amplitude from 2 V to 24 V rms. Total harmonic distortion is typically −50 dB.

The AD698 decodes LVDTs by synchronously demodulating the amplitude modulated input (secondaries), A, and a fixed input reference (primary or sum of secondaries or fixed input), B. A common problem with earlier solutions was that any drift in the amplitude of the drive oscillator corresponds directly to a gain error in the output. The AD698, eliminates these errors by calculating the ratio of the LVDT output to its input excitation in order to cancel out any drift effects. This device differs from the AD598 LVDT signal conditioner in that it implements a different circuit transfer function and does not require the sum of the LVDT secondaries (A + B) to be constant with stroke length.

The AD698 block diagram is shown below. The inputs consist of two independent synchronous demodulation channels. The B channel is designed to monitor the drive excitation to the LVDT. The full wave rectified output is filtered by C2 and sent to the computational circuit. Channel A is identical except that the comparator is pinned out separately. Since the A channel may reach 0 V output at LVDT null, the A channel demodulator is usually triggered by the primary voltage, (B Channel). In addition, a phase compensation network may be required to add a phase lead or lag to the A Channel to compensate for the LVDT primary to secondary phase shift. For half-bridge circuits the phase shift is noncritical, and the A channel voltage is large enough to trigger the demodulator.

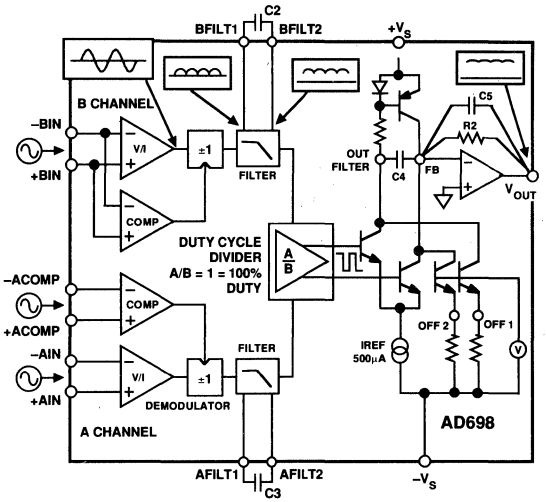

Figure 6. AD698 Block Diagram

Once both channels are demodulated and filtered a division circuit, implemented with a duty cycle multiplier, is used to calculate the ratio A/B. The output of the divider is a duty cycle. When A/B is equal to 1, the duty cycle will be equal to 100%. (This signal can be used as is if a pulse width modulated output is required.) The duty cycle drives a circuit that modulates and filters a reference current proportional to the duty cycle. The output amplifier scales the 500 μA reference current converting it to a voltage. The output transfer function is thus,

$$V_{OUT} = I_{REF} \times A/B \times R2, \text{ where } I_{REF} = 500\ \mu A$$

16

CONNECTING THE AD698

The AD698 can easily be connected for dual or single supply operation as shown in Figures 7 and 13. The following general design procedures demonstrate how external component values are selected and can be used for any LVDT that meets AD698 input/output criteria. The connections for the A and B channels and the A channel comparators will depend on which transducer is used. In general follow the guidelines below.

Parameters set with external passive components include: excitation frequency and amplitude, AD698 input signal frequency, and the scale factor (V/inch). Additionally, there are optional features; offset null adjustment, filtering, and signal integration, which can be implemented by adding external components.

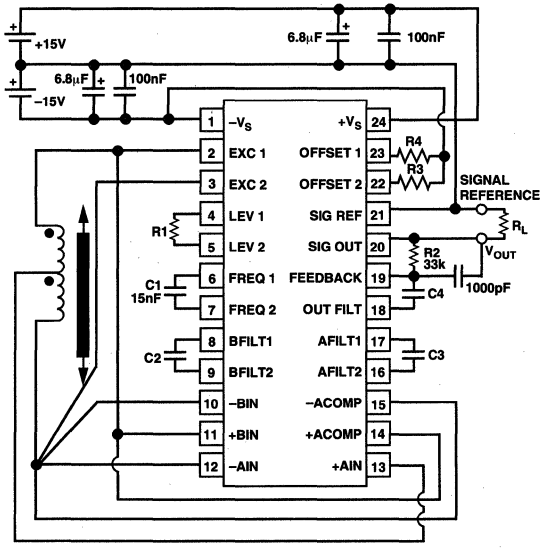

Figure 7. Interconnection Diagram for Half-Bridge LVDT and Dual Supply Operation

DESIGN PROCEDURE

DUAL SUPPLY OPERATION

Figure 7 shows the connection method for half-bridge LVDTs. Figure 8 demonstrates the connections for 3- and 4-wire LVDTs connected in the series opposed configuration. Both examples use dual ±15 volt power supplies.

A. Determine the Oscillator Frequency

Frequency is often determined by the required BW of the system. However, in some system the frequency is set to match the LVDT zero phase frequency as recommended by the manufacturer; in this case skip to Step 4.

1. Determine the mechanical bandwidth required for LVDT position measurement subsystem, $f_{SUBSYSTEM}$. For this example, assume $f_{SUBSYSTEM}$ = 250 Hz.
2. Select minimum LVDT excitation frequency approximately 10 × $f_{SUBSYSTEM}$. Therefore, let excitation frequency = 2.5 kHz.
3. Select a suitable LVDT that will operate with an excitation frequency of 2.5 kHz. The Schaevitz E100, for instance, will operate over a range of 50 Hz to 10 kHz and is an eligible candidate for this example.
4. Select excitation frequency determining component C1.

$$C1 = 35\ \mu F\ Hz/f_{EXCITATION}$$

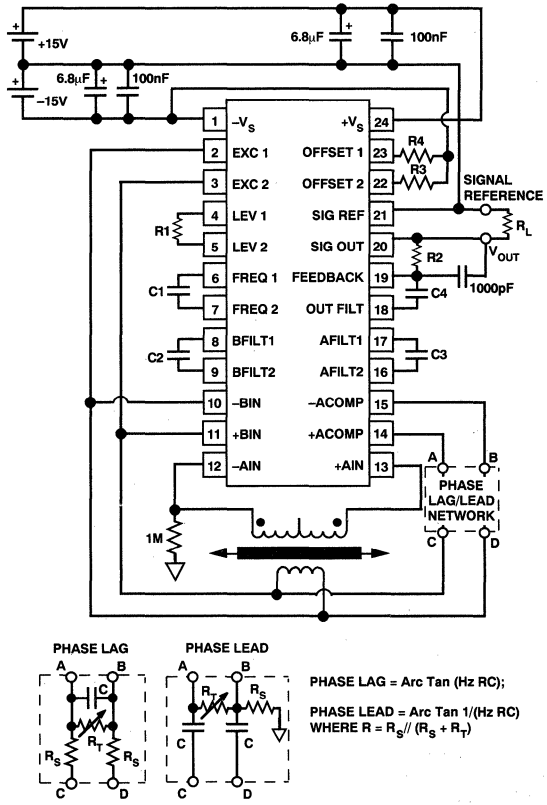

Figure 8. AD698 Interconnection Diagram for Series Opposed LVDT and Dual Supply Operation

B. Determine the Oscillator Amplitude

Amplitude is set such that the primary signal is in the 1.0 V to 3.5 V rms range and the secondary signal is in the 0.25 V to 3.5 V rms range when the LVDT is at its mechanical full-scale position. This optimizes linearity and minimizes noise susceptibility. Since the part is ratiometric, the exact value of the excitation is relatively unimportant.

5. Determine optimum LVDT excitation voltage, V_{EXC}. For a 4-wire LVDT determine the voltage transformation ratio, VTR, of the LVDT at its mechanical full scale. VTR = LVDT sensitivity × Maximum Stroke Length from null.

   LVDT sensitivity is listed in the LVDT manufacturer's catalog and has units of volts output per volts input per inch displacement. The E100 has a sensitivity of 2.4 mV/V/mil. In the event that LVDT sensitivity is not given by the manufacturer, it can be computed. See section on determining LVDT sensitivity.

Multiply the primary excitation voltage by the VTR to get the expected secondary voltage at mechanical full scale. For example, for an LVDT with a sensitivity of 2.4 mV/V/mil and a full scale of ±0.1 inch, the VTR = 0.0024 V/V/Mil × 100 mil = 0.24. Assuming the maximum excitation of 3.5 V rms, the maximum secondary voltage will be 3.5 V rms × 0.24 = 0.84 V rms, which is in the acceptable range.

Conversely the VTR may be measured explicitly. With the LVDT energized at its typical drive level V_{PRI}, as indicated by the manufacturer. Set the core displacement to its mechanical full-scale position and measure the output V_{SEC} of the secondary. Compute the LVDT voltage transformation ratio, VTR. VTR = V_{SEC}/V_{PRI}. For the E100, V_{SEC} = 0.72 V for V_{PRI} = 3 V. VTR = 0.24.

For situations where LVDT sensitivity is low, or the mechanical FS is a small fraction of the total stroke length an input excitation of more than 3.5 V rms may be needed. In this case a voltage divider network may be placed across the LVDT primary to provide smaller voltage for the +BIN and −BIN input. If, for example, a network was added to divide the B Channel input by 1/2 then the VTR should also be reduced by 1/2 for the purpose of component selection.

Check the power supply voltages by verifying that the peak values of V_A and V_B are at least 2.5 volts less than the voltages at $+V_S$ and $-V_S$.

6. Referring to Figure 9, for V_S = ±15 V, select the value of the amplitude determining component R1 as shown by the curve in Figure 9.

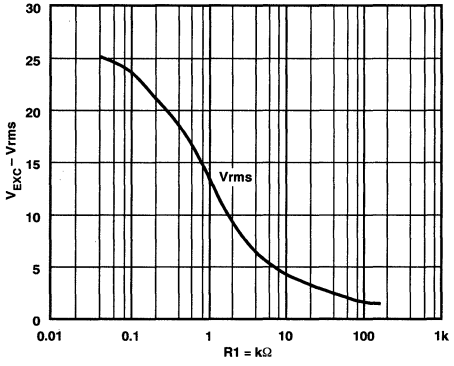

Figure 9. Excitation Voltage V_{EXC} vs. R1

C. Choose the Filter Capacitors: C2, C3, C4

7. C2, C3 and C4 are a function of the desired bandwidth of the AD698 position measurement subsystem. They should be nominally equal values.

$$C2 = C3 = C4 = 10^{-4}\ Farad\ Hz/f_{SUBSYSTEM}\ (Hz)$$

If the desired system bandwidth is 250 Hz, then

$$C2 = C3 = C4 = 10^{-4}\ Farad\ Hz/250\ Hz = 0.4\ \mu F$$

See Figures 14, 15 and 16 for more information about AD698 bandwidth and phase characterization.

D. Set the Full-Scale Output Voltage

8. Compute R2, which sets the AD698 gain or full-scale output range, several pieces of information are needed:

a. LVDT sensitivity, S

b. Full-scale core displacement from null, d

S × d = VTR and also equals the ratio A/B at mechanical full scale. The VTR should be converted to units of V/V.

For a full-scale displacement of d inches, voltage out of the AD698 is computed as

$$V_{OUT} = S \times d \times 500\ \mu A \times R2.$$

V_{OUT} is measured with respect to the signal reference, Pin 17 shown in Figure 7.

Solving for R2,

$$R2 = \frac{V_{OUT}}{S \times d \times 500\ \mu A} \quad (1)$$

For V_{OUT} = ±10 V full-scale range, (20 V span) and d = ±0.1 inch full-scale displacement, (0.2 inch span)

$$R2 = \frac{20\ V}{2.4 \times 0.2 \times 500\ \mu A} = 83.3\ k\Omega$$

V_{OUT} as a function of displacement for the above example is shown in Figure 10.

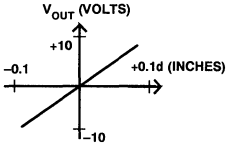

Figure 10. V_{OUT} (±10 V Full Scale) vs. Core Displacement (±0.1 Inch)

E. Optional Offset of Output Voltage Swing

9. Selections of R3 and R4 permit a positive or negative output voltage offset adjustment.

$$V_{OS} = 1.2\ V \times R2 \times \left(\frac{1}{R3 + 2\ k\Omega} - \frac{1}{R4 + 2\ k\Omega}\right) \quad (2)$$

For no offset adjustment R3 and R4 should be open circuit.

To design a circuit producing a 0 V to +10 V output for a displacement of ±0.1 inch, set V_{OUT} to +10 V, d = 0.2 inch and solve Equation (1) for R2.

$$R2 = 37.6\ k\Omega$$

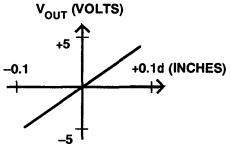

Figure 11. V_{OUT} (±5 V Full Scale) vs. Core Displacement (±0.1 Inch)

This will produce a response shown in Figure 11.

In Equation (2) set V_{OS} = 5 V and solve for R3 and R4. Since a positive offset is desired, let R4 be open circuit. Rearranging Equation (2) and solving for R3

$$R3 = \frac{1.2 \times R2}{V_{OS}} - 2\ k\Omega = 4.02\ k\Omega$$

16

Note that V_{OS} should be chosen so that R3 cannot have negative value.

Figure 12 shows the desired response.

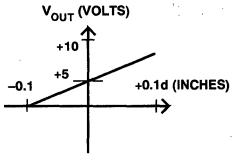

Figure 12. V_{OUT} (0 V–10 V Full Scale) vs. Displacement (±0.1 Inch)

DESIGN PROCEDURE

SINGLE SUPPLY OPERATION

Figure 13 shows the single supply connection method.

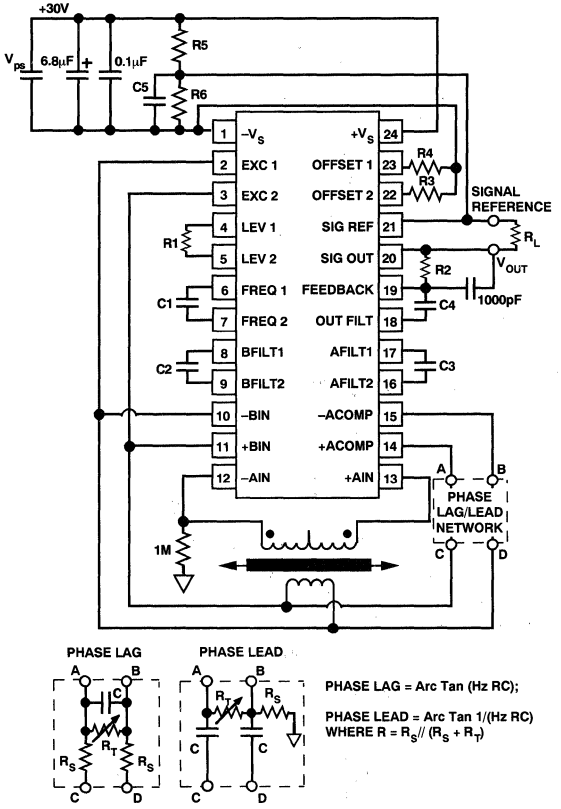

Figure 13. Interconnection Diagram for Single Supply Operation

For single supply operation, repeat Steps 1 through 10 of the design procedure for dual supply operation. R5, R6 and C5 are additional component values to be determined. V_{OUT} is measured with respect to SIGNAL REFERENCE.

10. Compute a maximum value of R5 and R6 based upon the relationship

$$R5 \pm R6 \leq V_{PS}/100\ \mu A$$

11. The voltage drop across R5 must be greater than

$$2 + 10\ k\Omega \left(\frac{1.2\ V}{R4 + 2\ k\Omega} + 250\ \mu A + \frac{V_{OUT}}{4 \times R2} \right) Volts$$

Therefore

$$R5 \geq \frac{2 + 10\ k\Omega \left(\frac{1.2\ V}{R4 + 2\ k\Omega} + 250\ \mu A + \frac{V_{OUT}}{4 \times R2} \right)}{100\ \mu A}\ Ohms$$

Based upon the constraints of R5 + R6 (Step 11) and R5 (Step 12), select an interim value of R6.

12. Load current through R_L returns to the junction of R5 and R6, and flows back to V_{PS}. Under maximum load conditions, make sure the voltage drop across R5 is met as defined in Step 11.

    As a final check on the power supply voltages, verify that the peak values of V_A and V_B are at least 2.5 volts less than the voltages at $+V_S$ and $-V_S$.

13. C5 is a bypass capacitor in the range of 0.1 µF to 1µF.

Gain Phase Characteristics

To use an LVDT in a closed loop mechanical servo application, it is necessary to know the dynamic characteristics of the transducer and interface elements. The transducer itself is very quick to respond once the core is moved. The dynamics arise primarily from the interface electronics. Figures 14, 15 and 16 show the frequency response of the AD698 LVDT Signal Conditioner. Note that Figures 15 and 16 are basically the same; the difference is frequency range covered. Figure 15 shows a wider range of mechanical input frequencies at the expense of accuracy.

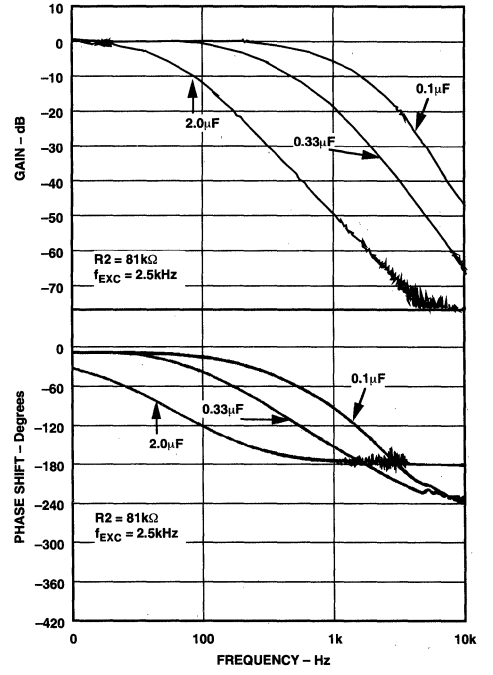

Figure 14. Gain and Phase Characteristics vs. Frequency (0 kHz–10 kHz)

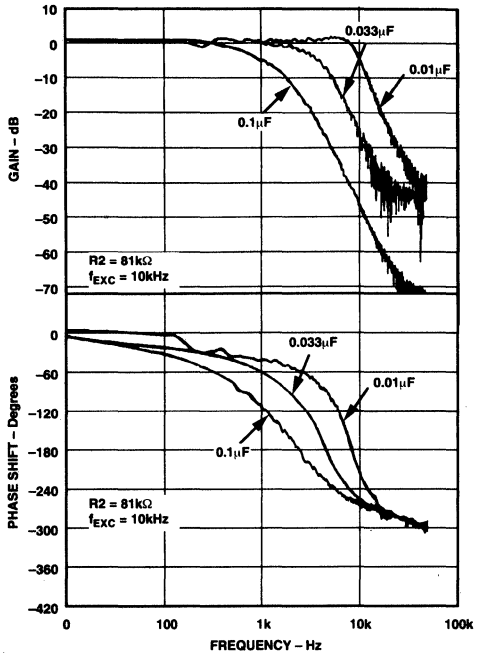

Figure 15. Gain and Phase Characteristics vs. Frequency (0 kHz–50 kHz)

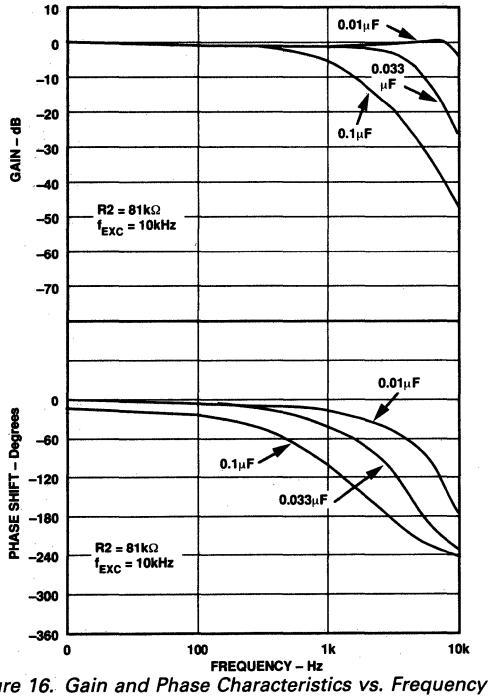

Figure 16. Gain and Phase Characteristics vs. Frequency (0 kHz–10 kHz)

Figure 16 shows a more limited frequency range with enhanced accuracy. The figures are transfer functions with the input to be considered as a sinusoidally varying mechanical position and the output as the voltage from the AD698; the units of the transfer function are volts per inch. The value of C2, C3, and C4, from Figure 7, are all equal and designated as a parameter in the figures. The response is approximately that of two real poles. However, there is appreciable excess phase at higher frequencies. An additional pole of filtering can be introduced with a shunt capacitor across R2, Figure 7; this will also increase phase lag.

When selecting values of C2, C3 and C4 to set the bandwidth of the system, a trade-off is involved. There is ripple on the "dc" position output voltage, and the magnitude is determined by the filter capacitors. Generally, smaller capacitors will give higher system bandwidth and larger ripple. Figures 17 and 18 show the magnitude of ripple as a function of C2, C3 and C4, again all equal in value. Note also a shunt capacitor across R2, Figure 7 is shown as a parameter. The value of R2 used was 81 kΩ with a Schaevitz E100 LVDT.

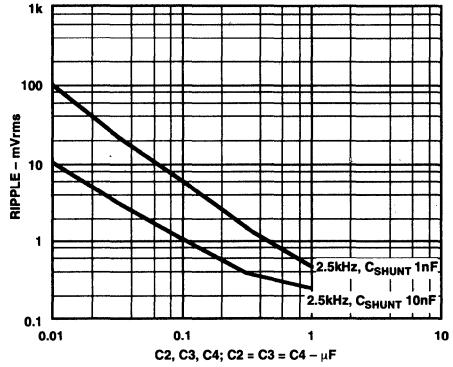

Figure 17. Output Voltage Ripple vs. Filter Capacitance

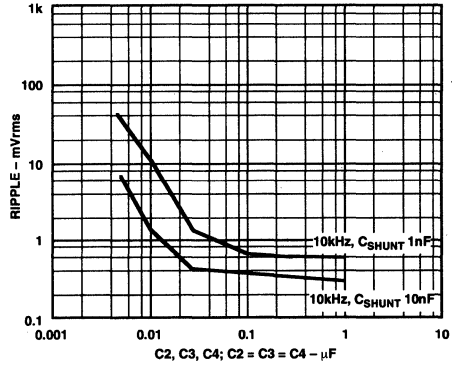

Figure 18. Output Voltage Ripple vs. Filter Capacitance

Determining LVDT Sensitivity
LVDT sensitivity can be determined by measuring the LVDT secondary voltages as a function of primary drive and core position, and performing a simple computation.

Energize the LVDT at its recommended primary drive level, V_{PRI} (3 V rms for the E100). Set the core displacement to its mechanical full-scale position and measure secondary voltages V_A and V_B.

$$Sensitivity = \frac{V_{SECONDARY}}{V_{PRI} \times d}$$

From Figure 19,

$$Sensitivity = \frac{0.84}{3.5\ V \times 100\ mils} = 2.4\ mV/V\ mil$$

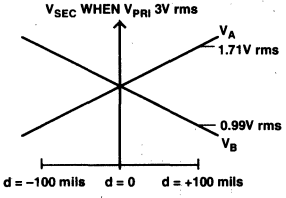

Figure 19. LVDT Secondary Voltage vs. Core Displacement

Thermal Shutdown and Loading Considerations.
The AD698 is protected by a thermal overload circuit. If the die temperature reaches 165°C the sine wave excitation amplitude gradually reduces, thereby lowering the internal power dissipation and temperature.

Due to the ratiometric operation of the decoder circuit, only small errors result from the reduction of the excitation amplitude. Under these conditions the signal-processing section of the AD698 continues to meet its output specifications

The thermal load depends upon the voltage and current delivered to the load as well as the power supply potentials. An LVDT Primary will present an inductive load to the sine wave excitation. The phase angle between the excitation voltage and current must also be considered, further complicating thermal calculations.

APPLICATIONS

Most of the applications for the AD598 can also be implemented with the AD698. Please refer to the applications written for the AD598 for a detailed explanation.

See AD598 data sheet for:

- Proving Ring-Weigh Scale

AC BRIDGE SIGNAL CONDITIONER

Bridge circuits which use dc excitation are often plagued by errors caused by thermocouple effects, 1/f noise, dc drifts in the electronics, and line noise pickup. One way to get around these problems is to excite the bridge with an ac waveform, amplify the bridge output with an ac amplifier, and synchronously demodulate the resulting signal. The ac phase and amplitude information from the bridge is recovered as a dc signal at the output of the synchronous demodulator. The low frequency system noise, dc drifts, and demodulator noise all get mixed to the carrier frequency and can be removed by means of a low pass filter.

The AD698 with the addition of a simple ac gain stage can be used to implement an ac bridge. Figure 20 shows the connections for such a system. The AD698 oscillator provide ac excitation for the bridge. The low level bridge signal is amplified by the gain stage created by A1, A2 to provide a differential input to the A Channel of the AD698. The signal is then synchronously detected by A Channel. The B Channel is used to detect the level of the bridge excitation. The ratio of A/B is then calculated and converted to an output voltage by R2. An optional phase lag/lead network can be added in front of the A comparator to adjust for phase delays through the bridge and the amplifier, or if the phase delay is small it can be ignored or compensated by a gain adjustment.

This circuit can be used for resistive bridges such as strain gages, or for inductive or capacitive bridges that are commonly used for pressure or flow sensors. The low level signal outputs of these sensors are susceptible to noise and interference and are good candidates for ac signal processing techniques.

Component Selection
Amplifiers A1, A2 will be chosen depending on the type of bridge that is conditioned. Capacitive bridges should use an amplifier with low bias current; a large bleeder resistor will be required from the amplifier inputs to ground to provide a path for the dc bias current. Resistive and inductive bridges can use a more general purpose amplifier. The dc performance of A1, A2 are not as important as their ac performance. DC errors such as voltage offset will be chopped out by the AD698 since they are not synchronous to the carrier frequency.

The oscillator amplitude and span resistor for the AD698 may be chosen by first computing the transfer function or sensitivity of the bridge and the ac amplifier. This ratio will correspond to the A/B term in the AD698 transfer function. For example, suppose that a resistive strain gage with a sensitivity, S, of 2 mV/V at full scale is used. Select an arbitrary target value for A/B that is close to its maximum value such as A/B = 0.8. Then choose a gain for the ac amplifier so that the strain gage transfer function from excitation to output also equals 0.8. Thus the required amplifier gain will be [A/B]/ S; or 0.8 / 0.002V/V = 400. Then select values for R_S and R_G. For the gain stage:

$$V_{OUT} = \left[\frac{2 \times R_S}{R_G + 1}\right] \times V_{IN}$$

Solving for V_{OUT}/V_{IN} = 400 and setting R_G = 100 Ω then:

$$R_S = [400\text{-}1] \times R_G/2 = 19.95\ k\Omega$$

Choose an oscillator amplitude that is in the range of 1 V to 3.5 V rms. For an input excitation level of 3 V rms the output signal from the amplifier gain stage will be 3.5 V rms × 0.8 V or 2.4V rms, which is in the acceptable range.

Since A/B is known, the value of R2, the output FS resistor may be chosen by the formula:

$$V_{OUT} = A/B \times 500\ \mu A \times R2$$

For a 10 V output at FS, with an A/B of 0.8; solve for R2.

$$R2 = 10\ V/[0.8 \times 500\ \mu A] = 25.0\ k\Omega$$

This will result in a V_{OUT} of 10 V for a full-scale signal from the bridge. The other components, C1, C2, C3, C4 may be selected by following the guidelines on general device operation mentioned earlier.

If a gain trim is required, then a trim resistor can be used to adjust either R2 or R_G. Bridge offsets should be adjusted by a trim network on the OFFSET 1 and OFFSET 2 pins of the AD698.

ANALOG DEVICES

Internally Trimmed Precision IC Multiplier

AD534

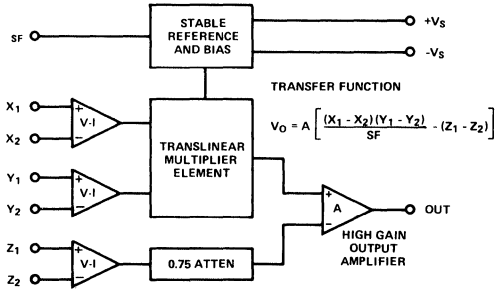
FEATURES

Pretrimmed to ±0.25% max 4-Quadrant Error (AD534L)
All Inputs (X, Y and Z) Differential, High Impedance for $[(X_1-X_2)(Y_1-Y_2)/10V]+Z_2$ Transfer Function
Scale-Factor Adjustable to Provide up to X100 Gain
Low Noise Design: 90μV rms, 10Hz-10kHz
Low Cost, Monolithic Construction
Excellent Long Term Stability

APPLICATIONS

High Quality Analog Signal Processing
Differential Ratio and Percentage Computations
Algebraic and Trigonometric Function Synthesis
Wideband, High-Crest rms-to-dc Conversion
Accurate Voltage Controlled Oscillators and Filters
Available in Chip Form

FUNCTIONAL BLOCK DIAGRAM



PRODUCT DESCRIPTION

The AD534 is a monolithic laser trimmed four-quadrant multiplier divider having accuracy specifications previously found only in expensive hybrid or modular products. A maximum multiplication error of ±0.25% is guaranteed for the AD534L without any external trimming. Excellent supply rejection, low temperature coefficients and long term stability of the on-chip thin film resistors and buried zener reference preserve accuracy even under adverse conditions of use. It is the first multiplier to offer fully differential, high impedance operation on all inputs, including the Z-input, a feature which greatly increases its flexibility and ease of use. The scale factor is pretrimmed to the standard value of 10.00V; by means of an external resistor, this can be reduced to values as low as 3V.

The wide spectrum of applications and the availability of several grades commend this multiplier as the first choice for all new designs. The AD534J (±1% max error), AD534K (±0.5% max) and AD534L (±0.25% max) are specified for operation over the 0 to +70°C temperature range. The AD534S (±1% max) and AD534T (±0.5% max) are specified over the extended temperature range, -55°C to +125°C. All grades are available in hermetically sealed TO-100 metal cans and TO-116 ceramic DIP packages. AD534J, K, S and T chips are also available.

PROVIDES GAIN WITH LOW NOISE

The AD534 is the first general purpose multiplier capable of providing gains up to X100, frequently eliminating the need for separate instrumentation amplifiers to precondition the inputs. The AD534 can be very effectively employed as a variable gain differential input amplifier with high common mode rejection. The gain option is available in all modes, and will be found to simplify the implementation of many function-fitting algorithms such as those used to generate sine and tangent. The utility of this feature is enhanced by the inherent low noise of the AD534: 90μV, rms (depending on the gain), a factor of 10 lower than previous monolithic multipliers. Drift and feedthrough are also substantially reduced over earlier designs.

UNPRECEDENTED FLEXIBILITY

The precise calibration and differential Z-input provide a degree of flexibility found in no other currently available multiplier. Standard MDSSR functions (multiplication, division, squaring, square-rooting) are easily implemented while the restriction to particular input/output polarities imposed by earlier designs has been eliminated. Signals may be summed into the output, with or without gain and with either a positive or negative sense. Many new modes based on implicit-function synthesis have been made possible, usually requiring only external passive components. The output can be in the form of a current, if desired, facilitating such operations as integration.

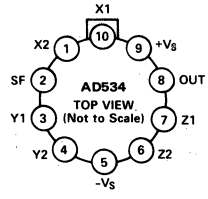
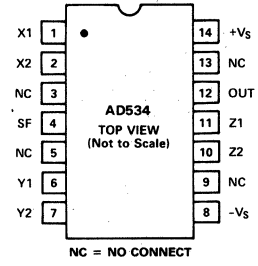
PIN CONFIGURATIONS

TO-100 (H-10A) Package

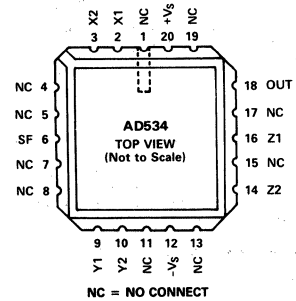


TO-116 (D-14) Package



NC = NO CONNECT

LCC (E-20A) Package



NC = NO CONNECT

ANALOG DEVICES

Low Cost Analog Multiplier

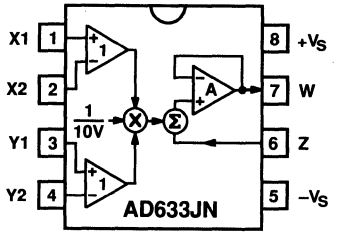
AD633

FEATURES
Four-Quadrant Multiplication
Low Cost 8-Pin Package
Complete—No External Components Required
Laser-Trimmed Accuracy and Stability
Total Error Within 2% of FS
Differential High Impedance X and Y Inputs
High Impedance Unity-Gain Summing Input
Laser-Trimmed 10 V Scaling Reference

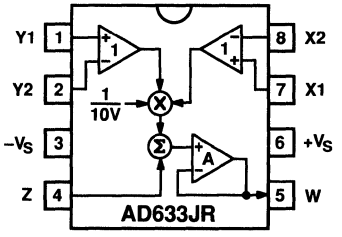
APPLICATIONS
Multiplication, Division, Squaring
Modulation/Demodulation, Phase Detection
Voltage-Controlled Amplifiers/Attenuators/Filters

CONNECTION DIAGRAMS

8-Pin Plastic DIP (N) Package



8-Pin Plastic SOIC (R) Package



$$W = \frac{(X_1 - X_2)(Y_1 - Y_2)}{10V} + Z$$

PRODUCT DESCRIPTION

The AD633 is a functionally complete, four-quadrant, analog multiplier. It includes high impedance, differential X and Y inputs and a high impedance summing input (Z). The low impedance output voltage is a nominal 10 V full scale provided by a buried Zener. The AD633 is the first product to offer these features in modestly priced 8-pin plastic DIP and SOIC packages.

The AD633 is laser calibrated to a guaranteed total accuracy of 2% of full scale. Nonlinearity for the Y-input is typically less than 0.1% and noise referred to the output is typically less than 100 μV rms in a 10 Hz to 10 kHz bandwidth. A 1 MHz bandwidth, 20 V/μs slew rate, and the ability to drive capacitive loads make the AD633 useful in a wide variety of applications where simplicity and cost are key concerns.

The AD633's versatility is not compromised by its simplicity. The Z-input provides access to the output buffer amplifier, enabling the user to sum the outputs of two or more multipliers, increase the multiplier gain, convert the output voltage to a current, and configure a variety of applications.

The AD633 is available in an 8-pin plastic mini-DIP package (N) and 8-pin SOIC (R) and is specified to operate over the 0°C to +70°C commercial temperature range.

PRODUCT HIGHLIGHTS

1. The AD633 is a complete four-quadrant multiplier offered in low cost 8-pin plastic packages. The result is a product that is cost effective and easy to apply.
2. No external components or expensive user calibration are required to apply the AD633.
3. Monolithic construction and laser calibration make the device stable and reliable.
4. High (10 MΩ) input resistances make signal source loading negligible.
5. Power supply voltages can range from ±8 V to ±18 V. The internal scaling voltage is generated by a stable Zener diode; multiplier accuracy is essentially supply insensitive.

ANALOG DEVICES

10 MHz, 4-Quadrant Multiplier/Divider

AD734

FEATURES

High Accuracy
- **0.1% Typical Error**

High Speed
- **10 MHz Full-Power Bandwidth**
- **450 V/μs Slew Rate**
- **200 ns Settling to 0.1% at Full Power**

Low Distortion
- **−80 dBc from Any Input**
- **Third-Order IMD Typically −75 dBc at 10 MHz**

Low Noise
- **94 dB SNR, 10 Hz to 20 kHz**
- **70 dB SNR, 10 Hz to 10 MHz**

Direct Division Mode
- **2 MHz BW at Gain of 100**

APPLICATIONS

High Performance Replacement for AD534
Multiply, Divide, Square, Square Root
Modulator, Demodulator
Wideband Gain Control, RMS-DC Conversion
Voltage-Controlled Amplifiers, Oscillators, and Filters
Demodulator with 40 MHz Input Bandwidth

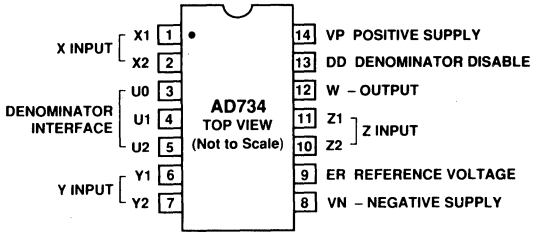
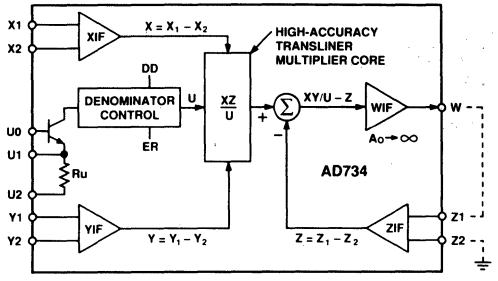
14-Pin DIP
(Q Package) & (N Package)



FUNCTIONAL BLOCK DIAGRAM



PRODUCT DESCRIPTION

The AD734 is an accurate high speed, four-quadrant analog multiplier that is pin-compatible with the industry-standard AD534 and provides the transfer function W = XY/U. The AD734 provides a low-impedance voltage output with a full-power (20 V pk–pk) bandwidth of 10 MHz. Total static error (scaling, offsets, and nonlinearities combined) is 0.1% of Full Scale. Distortion is typically less than −80 dBc and guaranteed. The low-capacitance X, Y and Z inputs are fully differential. In most applications, no external components are required to define the function.

The internal scaling (denominator) voltage U is 10 V, derived from a buried-Zener voltage reference. A new feature provides the option of substituting an external denominator voltage, allowing the use of the AD734 as a two-quadrant divider with a 1000:1 denominator range and a signal bandwidth that remains 10 MHz to a gain of 20 dB, 2 MHz at a gain of 40 dB and 200 kHz at a gain of 60 dB, for a gain-bandwidth product of 200 MHz.

The advanced performance of the AD734 is achieved by a combination of new circuit techniques, the use of a high speed complementary bipolar process and a novel approach to laser-trimming based on ac signals rather than the customary dc methods. The wide bandwidth (>40 MHz) of the AD734's input stages and the 200 MHz gain-bandwidth product of the multiplier core allow the AD734 to be used as a low distortion demodulator with input frequencies as high as 40 MHz as long as the desired output frequency is less than 10 MHz.

The AD734AQ and AD734BQ are specified for the industrial temperature range of −40°C to +85°C and come in a 14-pin ceramic DIP. The AD734SQ/883B, available processed to MIL-STD-883B for the military range of −55°C to +125°C, is available in a 14-pin ceramic DIP.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

PRODUCT HIGHLIGHTS

The AD734 embodies more than two decades of experience in the design and manufacture of analog multipliers, to provide:

1. A new output amplifier design with more than twenty times the slew-rate of the AD534 (450 V/μs versus 20 V/μs) for a full power (20 V pk–pk) bandwidth of 10 MHz.
2. Very low distortion, even at full power, through the use of circuit and trimming techniques that virtually eliminate all of the spurious nonlinearities found in earlier designs.
3. Direct control of the denominator, resulting in higher multiplier accuracy and a gain-bandwidth product at small denominator values that is typically 200 times greater than that of the AD534 in divider modes.
4. Very clean transient response, achieved through the use of a novel input stage design and wide-band output amplifier, which also ensure that distortion remains low even at high frequencies.
5. Superior noise performance by careful choice of device geometries and operating conditions, which provide a guaranteed 88 dB of dynamic range in a 20 kHz bandwidth.

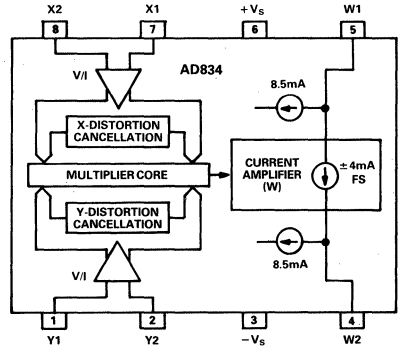
500MHz Four-Quadrant Multiplier

AD834

FEATURES
DC to >500MHz Operation
Differential ±1V Full Scale Inputs
Differential ±4mA Full Scale Output Current
Low Distortion (≤0.05% for 0dBm Input)
Supply Voltages from ±4V to ±9V
Low Power (280mW typical at V_S=±5V)

APPLICATIONS
High Speed Real Time Computation
Wideband Modulation and Gain Control
Signal Correlation and RF Power Measurement
Voltage Controlled Filters and Oscillators
Linear Keyers for High Resolution Television
Wideband True RMS

FUNCTIONAL BLOCK DIAGRAM



PRODUCT DESCRIPTION

The AD834 is a monolithic laser-trimmed four-quadrant analog multiplier intended for use in high frequency applications, having a transconductance bandwidth (R_L=50Ω) in excess of 500MHz from either of the differential voltage inputs. In multiplier modes, the typical total full scale error is 0.5%, dependent on the application mode and the external circuitry. Performance is relatively insensitive to temperature and supply variations, due to the use of stable biasing based on a bandgap reference generator and other design features.

To preserve the full bandwidth potential of the high speed bipolar process used to fabricate the AD834, the outputs appear as a differential pair of currents at open collectors. To provide a single ended ground referenced voltage output, some form of external current to voltage conversion is needed. This may take the form of a wideband transformer, balun, or active circuitry such as an op amp. In some applications (such as power measurement) the subsequent signal processing may not need to have high bandwidth.

The transfer function is accurately trimmed such that when X=Y=±1V, the differential output is ±4mA. This absolute calibration allows the outputs of two or more AD834s to be summed with precisely equal weighting, independent of the accuracy of the load circuit.

The AD834J is specified for use over the commercial temperature range of 0 to +70°C and is available in an 8-pin plastic DIP package and an 8-pin plastic SOIC package. AD834A is available in cerdip for operation over the industrial temperature range of −40°C to +85°C. The AD834S/883B is specified for operation over the military temperature range of −55°C to +125°C and is available in the 8-pin cerdip package. S-Grade chips are also available.

Two application notes featuring the AD834 (AN-212 and AN-216) can now be obtained by calling 1-800-ANALOG-D. For additional applications circuits, consult the AD811 data sheet.

PRODUCT HIGHLIGHTS

1. The AD834 combines high static accuracy (low input and output offsets and accurate scale factor) with very high bandwidth. As a four-quadrant multiplier or squarer, the response extends from dc to an upper frequency limited mainly by packaging and external board layout considerations. A large signal bandwidth of over 500MHz is attainable under optimum conditions.
2. The AD834 can be used in many high speed nonlinear operations, such as square rooting, analog division, vector addition and rms-to-dc conversion. In these modes, the bandwidth is limited by the external active components.
3. Special design techniques result in low distortion levels (better than −60dB on either input) at high frequencies and low signal feedthrough (typically −65dB up to 20MHz).
4. The AD834 exhibits low differential phase error over the input range—typically 0.08° at 5MHz and 0.8° at 50MHz. The large signal transient response is free from overshoot, and has an intrinsic rise time of 500ps, typically settling to within 1% in under 5ns.
5. The nonloading, high impedance, differential inputs simplify the application of the AD834.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

NOTES

[1]Error is defined as the maximum deviation from the ideal output, and expressed as a percentage of the full scale output.

[2]Both supplies taken simultaneously; sinusoidal input at f≤10kHz.

[3]Linearity is defined as residual error after compensating for input offset voltage, output offset current and scaling current errors.

[4]Bandwidth is guaranteed when configured in squarer mode. See Figure 5.

[5]Sine input; relative to full scale output; zero input port nulled; represents feedthrough of the fundamental.

[6]Negative supply current is equal to the sum of positive supply current, the signal currents into each output, W1 and W2, and the input bias currents.

Specifications in **boldface** are tested on all production units at final electrical test. Results from those tests are used to calculate outgoing quality levels.

Specifications subject to change without notice.

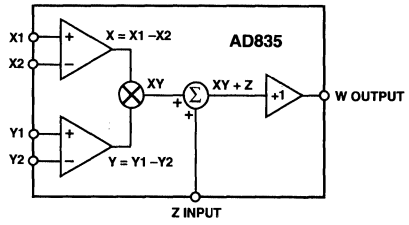
250 MHz, Voltage Output 4-Quadrant Multiplier

AD835

FEATURES
Simple: Basic Function is W = XY + Z
Complete: Minimal External Components Required
Very Fast: Settles to 0.1% of FS in 20 ns
DC-Coupled Voltage Output Simplifies Use
High Differential Input Impedance X, Y and Z Inputs
Low Multiplier Noise: 50 nV/$\sqrt{Hz}$

APPLICATIONS
Very Fast Multiplication, Division, Squaring
Wideband Modulation and Demodulation
Phase Detection and Measurement
Sinusoidal Frequency Doubling
Video Gain Control and Keying
Voltage Controlled Amplifiers and Filters

FUNCTIONAL BLOCK DIAGRAM



PRODUCT DESCRIPTION

The AD835 is a complete four-quadrant voltage output analog multiplier fabricated on an advanced dielectrically isolated complementary bipolar process. It generates the linear product of its X and Y voltage inputs, with a –3 dB output bandwidth of 250 MHz (a small signal rise time of 1 ns). Full-scale (–1 V to +1 V) rise/fall times are 2.5 ns (with the standard R_L of 150 Ω) and the settling time to 0.1% under the same conditions is typically 20 ns.

Its differential multiplication inputs (X, Y) and its summing input (Z) are at high impedance. The low impedance output voltage (W) can provide up to ±2.5 V and drive loads as low as 25 Ω. Normal operation is from ±5 V supplies.

Though providing state-of-the-art speed, the AD835 is simple to use and versatile. For example, as well as permitting the addition of a signal at the output, the Z input provides the means to operate the AD835 with voltage gains up to about ×10. In this capacity, the very low product noise of this multiplier (50 nV$\sqrt{Hz}$) makes it much more useful than earlier products.

The AD835 is available in an 8-pin plastic mini-DIP package (N) and an 8-pin SOIC (R) and is specified to operate over the –40°C to +85°C industrial temperature range.

PRODUCT HIGHLIGHTS

1. The AD835 is the first monolithic 250 MHz four quadrant voltage output multiplier.
2. Minimal external components are required to apply the AD835 to a variety of signal processing applications.
3. High input impedances (100 kΩ‖2 pF) make signal source loading negligible.
4. High output current capability allows low impedance loads to be driven.
5. State of the art noise levels achieved through careful device optimization and the use of a special low noise bandgap voltage reference.
6. Designed to be easy to use and cost effective in applications which formerly required the use of hybrid or board level solutions.

PRODUCT DESCRIPTION

The AD835 is a four-quadrant, voltage output, analog multiplier fabricated on an advanced, dielectrically isolated, complementary bipolar process. In its basic mode, it provides the linear product of its X and Y voltage inputs. In this mode, the –3 dB output voltage bandwidth is 250 MHz (a small signal rise time of 1 ns). Full-scale (–1 V to +1 V) rise/fall times are 2.5 ns (with the standard R_L of 150 Ω) and the settling time to 0.1% under the same conditions is typically 20 ns.

As in earlier multipliers from Analog Devices, a unique summing feature is provided at the Z-input. As well as providing independent ground references for inputs and output, and enhanced versatility, this feature allows the AD835 to operate with voltage gain. Its X-, Y- and Z-input voltages are all nominally ±1 V FS, with overrange of at least 20%. The inputs are fully differential and at high impedance (100 kΩ‖2 pF) and provide a 70 dB CMRR (f ≤ 1 MHz).

The low impedance output is capable of driving loads as small as 25 Ω. The peak output can be as large as ±2.2 V minimum for R_L = 150 Ω, or ±2.0 V minimum into R_L = 50 Ω. The AD835 has much lower noise than the AD534 or AD734, making it attractive in low level signal-processing applications, for example, as a wideband gain-control element or modulator.

Basic Theory

The multiplier is based on a classic form, having a translinear core, supported by three (X, Y, Z) linearized voltage-to-current converters, and the load driving output amplifier. The scaling voltage (the denominator U, in the equations below) is provided by a bandgap reference of novel design, optimized for ultralow noise. Figure 17 shows the functional block diagram.

In general terms, the AD835 provides the function

$$W = \frac{(X1 - X2)(Y1 - Y2)}{U} + Z \qquad (1)$$

where the variables W, U, X, Y and Z are all voltages. Connected as a simple multiplier, with X = X1 – X2, Y = Y1 – Y2 and Z = 0, and with a scale factor adjustment (see below) which sets U = 1 V, the output can be expressed as

$$W = XY \qquad (2)$$

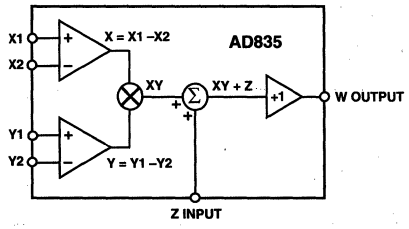

Figure 17. Functional Block Diagram

Simplified representations of this sort, where all signals are presumed to be expressed in *volts*, are used throughout this data sheet, to avoid the needless use of less-intuitive subscripted variables (such as V_{X1}). We can view all variables as being *normalized to 1 V*. For example, the input X can either be stated as being in the range –1 V to +1 V, or simply –1 to +1. The latter representation will be found to facilitate the development of new functions using the AD835. The explicit inclusion of the denominator, U, is also less helpful, as in the case of the AD835, if it is not an electrical input variable.

Scaling Adjustment

The basic value of U in Equation 1 is nominally 1.05 V. Figure 18, which shows the basic multiplier connections, also shows how the effective value of U can be adjusted to have any lower voltage (usually 1 V) through the use of a resistive-divider between W (Pin 5) and Z (Pin 4). Using the general resistor values shown, we can rewrite Equation 1 as

$$W = \frac{XY}{U} + kW + (1 - k)Z' \qquad (3)$$

(where Z' is distinguished from the signal Z at Pin 4). It follows that

$$W = \frac{XY}{(1 - k)U} + Z' \qquad (4)$$

In this way, we can modify the effective value of U to

$$U' = (1 - k)U \qquad (5)$$

without altering the scaling of the Z' input. (This is to be expected, since the only "ground reference" for the output is through the Z' input.)

Thus, to set U' to 1 V, remembering that the basic value of U is 1.05 V, we need to choose R1 to have a nominal value of 20 times R2. The values shown here allow U to be adjusted through the nominal range 0.95 V to 1.05 V, that is, R2 provides a 5% gain adjustment.

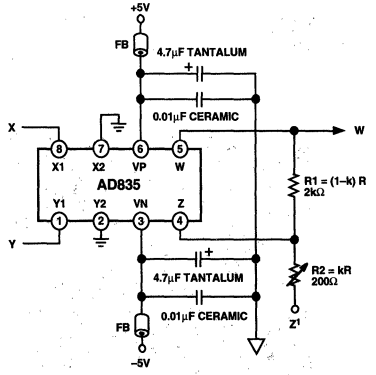

Figure 18. Multiplier Connections

Note that in many applications, the exact gain of the multiplier may not be very important; in which case, this network may be omitted entirely, or R2 fixed at 100 Ω.

Four-Channel, Four-Quadrant Analog Multiplier

MLT04

FEATURES

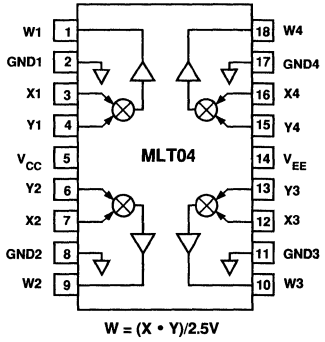
- Four Independent Channels
- Voltage IN, Voltage OUT
- No External Parts Required
- 8 MHz Bandwidth
- Four-Quadrant Multiplication
- Voltage Output; W = (X × Y)/2.5 V
  - 0.2% Typical Linearity Error on X or Y Inputs
- Excellent Temperature Stability: 0.005%
- ±2.5 V Analog Input Range
- Operates from ±5 V Supplies
- Low Power Dissipation: 150 mW typ
- Spice Model Available

APPLICATIONS

- Geometry Correction in High-Resolution CRT Displays
- Waveform Modulation & Generation
- Voltage Controlled Amplifiers
- Automatic Gain Control
- Modulation and Demodulation

FUNCTIONAL BLOCK DIAGRAM

18-Lead Epoxy DIP (P Suffix)
18-Lead Wide Body SOIC (S Suffix)



GENERAL DESCRIPTION

The MLT04 is a complete, four-channel, voltage output analog multiplier packaged in an 18-pin DIP or SOIC-18. These complete multipliers are ideal for general purpose applications such as voltage controlled amplifiers, variable active filters, "zipper" noise free audio level adjustment, and automatic gain control. Other applications include cost-effective multiple-channel power calculations (I × V), polynomial correction generation, and low frequency modulation. The MLT04 multiplier is ideally suited for generating complex, high-order waveforms especially suitable for geometry correction in high-resolution CRT display systems.

Fabricated in a complementary bipolar process, the MLT04 includes four 4-quadrant multiplying cells which have been laser-trimmed for accuracy. A precision internal bandgap reference normalizes signal computation to a 0.4 scale factor. Drift over temperature is under 0.005%/°C. Spot noise voltage of 0.3 μV/√Hz results in a THD + Noise performance of 0.02% (LPF = 22 kHz) for the lower distortion Y channel. The four 8 MHz channels consume a total of 150 mW of quiescent power.

The MLT04 is available in 18-pin plastic DIP, and SOIC-18 surface mount packages. All parts are offered in the extended industrial temperature range (–40°C to +85°C).

FUNCTIONAL DESCRIPTION

The MLT04 is a low cost quad, 4-quadrant analog multiplier with single-ended voltage inputs and voltage outputs. The functional block diagram for each of the multipliers is illustrated in Figure 3. Due to packaging constraints, access to internal nodes for externally adjusting scale factor, output offset voltage, or additional summing signals is not provided.

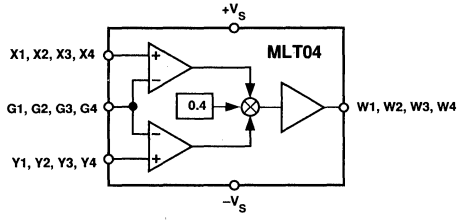

Figure 3. Functional Block Diagram of Each MLT04 Multiplier

Each of the MLT04's analog multipliers is based on a Gilbert cell multiplier configuration, a 1.23 V bandgap reference, and a unity-connected output amplifier. Multiplier scale factor is determined through a differential pair/trimmable resistor network external to the core. An equivalent circuit for each of the multipliers is shown in Figure 4.

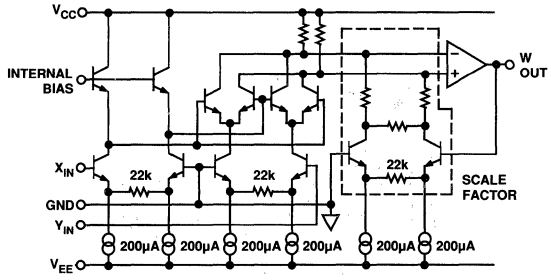

Figure 4. Equivalent Circuit for the MLT04

Details of each multiplier's output-stage amplifier are shown in Figure 5. The output stages idles at 200 µA, and the resistors in series with the emitters of the output stage are 25 Ω. The output stage can drive load capacitances up to 500 pF without oscillation. For loads greater than 500 pF, the outputs of the MLT04 should be isolated from the load capacitance with a 100 Ω resistor.

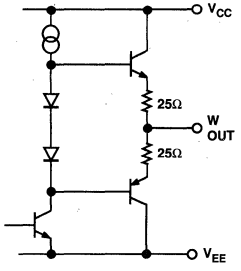

Figure 5. Equivalent Circuit for MLT04 Output Stages

ANALOG MULTIPLIER ERROR SOURCES

Multiplier errors consist primarily of input and output offsets, scale factor errors, and nonlinearity in the multiplying core. An expression for the output of a *real* analog multiplier is given by:

$$V_O = (K + \Delta K)\{(V_X + X_{OS})(V_Y + Y_{OS}) + Z_{OS} + f(X, Y)\}$$

where:
- K = Multiplier Scale Factor
- ΔK = Scale Factor Error
- V_X = X-Input Signal
- X_{OS} = X-Input Offset Voltage
- V_Y = Y-Input Signal
- Y_{OS} = Y-Input Offset Voltage
- Z_{OS} = Multiplier Output Offset Voltage
- $f(X, Y)$ = Nonlinearity

Executing the algebra to simplify the above expression yields expressions for all the errors in an analog multiplier:

Term	Description	Dependence on Input
KV_XV_Y	True Product	Goes to Zero As Either or Both Inputs Go to Zero
ΔKV_YV_Y	Scale-Factor Error	Goes to Zero at V_X, $V_Y = 0$
V_XY_{OS}	Linear "X" Feedthrough Due to Y-Input Offset	Proportional to V_X
V_YX_{OS}	Linear "Y" Feedthrough Due to X-Input Offset	Proportional to V_Y
$X_{OS}Y_{OS}$	Output Offset Due to X-, Y-Input Offsets	Independent of V_X, V_Y
Z_{OS}	Output Offset	Independent of V_X, V_Y
$f(X, Y)$	Nonlinearity	Depends on Both V_X, V_Y. Contains Terms Dependent on V_X, V_Y, Their Powers and Cross Products

As shown in the table, the primary static errors in an analog multiplier are input offset voltages, output offset voltage, scale factor, and nonlinearity. Of the four sources of error, only two are externally trimmable in the MLT04: the X- and Y-input offset voltages. Output offset voltage in the MLT04 is factory-trimmed to ±50 mV, and the scale factor is internally adjusted to ±2.5% of full scale. Input offset voltage errors can be eliminated by using the optional trim circuit of Figure 6. This scheme then reduces the net error to output offset, scale-factor (gain) error, and an irreducible nonlinearity component in the multiplying core.

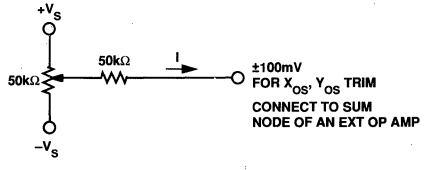

Figure 6. Optional Offset Voltage Trim Configuration

17

Feedthrough

In the ideal case, the output of the multiplier should be zero if either input is zero. In reality, some portion of the nonzero input will "feedthrough" the multiplier and appear at the output. This is caused by the product of the nonzero input and the offset voltage of the "zero" input. Introducing an offset equal to and opposite of the "zero" input offset voltage will null the linear component of the feedthrough. Residual feedthrough at the output of the multiplier is then irreducible core nonlinearity.

Typical X- and Y-input feedthrough curves for the MLT04 are shown in Figures 7 and 8, respectively. These curves illustrate MLT04 feedthrough after "zero" input offset voltage trim. Residual X-input feedthrough measures 0.08% of full scale, whereas residual Y-input feedthrough is almost immeasurable.

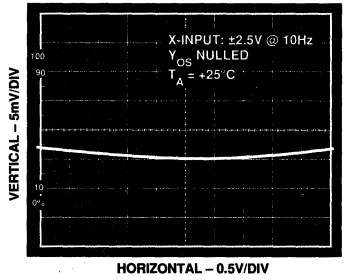

Figure 7. X-Input Feedthrough with Y_{os} Nulled

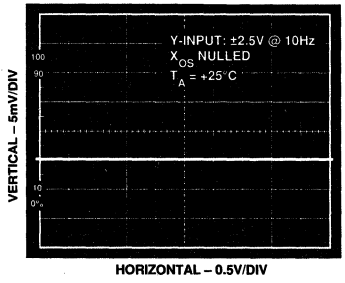

Figure 8. Y-Input Feedthrough with X_{os} Nulled

Nonlinearity

Multiplier core nonlinearity is the irreducible component of error. It is the difference between actual performance and "best-straight-line" theoretical output, for all pairs of input values. It is expressed as a percentage of full scale with all other dc errors nulled. Typical X- and Y-input nonlinearities for the MLT04 are shown in Figures 9 through 12. Worst-case X-input nonlinearity measured less than 0.2%, and Y-input nonlinearity measured better than 0.06%. For modulator/demodulator or mixer applications it is, therefore, recommended that the carrier be connected to the X-input while the signal is applied to the Y-input.

APPLICATIONS

The MLT04 is well suited for such applications as modulation/demodulation, automatic gain control, power measurement, analog computation, voltage-controlled amplifiers, frequency doublers, and geometry correction in CRT displays.

Multiplier Connections

Figure 43 llustrates the basic connections for multiplication. Each of the four independent multipliers has single-ended voltage inputs (X, Y) and a low impedance voltage output (W). Also, each multiplier has its own dedicated ground connection (GND) which is connected to the circuit's analog common. For best performance, circuit layout should be compact with short component leads and well-bypassed supply voltage feeds. In applications where fewer than four multipliers are used, all unused analog inputs must be returned to the analog common.

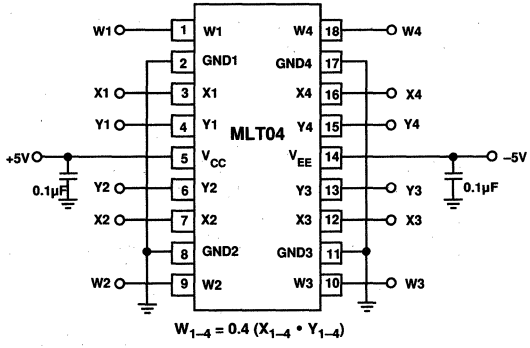

Figure 43. Basic Multiplier Connections

Squaring and Frequency Doubling

As shown in Figure 44, squaring of an input signal, V_{IN}, is achieved by connecting the X-and Y-inputs in parallel to produce an output of $V_{IN}^2/2.5$ V. The input may have either polarity, but the output will be positive.

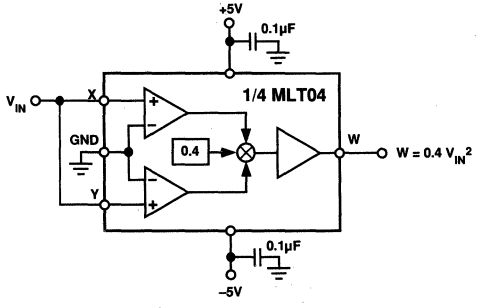

Figure 44. Connections for Squaring

When the input is a sine wave given by V_{IN} sin ωt, the squaring circuit behaves as a frequency doubler because of the trigonometric identity:

$$\frac{(V_{IN}\sin\omega t)^2}{2.5\,V} = \frac{V_{IN}^2}{2.5\,V}\left(\frac{1}{2}\right)(1-\cos 2\omega t)$$

The equation shows a dc term at the output which will vary strongly with the amplitude of the input, V_{IN}. The output dc offset can be eliminated by capacitively coupling the MLT04's output with a high-pass filter. For optimal spectral performance, the filter's cutoff frequency should be chosen to eliminate the input fundamental frequency.

A source of error in this configuration is the offset voltages of the X and Y inputs. The input offset voltages produce cross products with the input signal to distort the output waveform. To circumvent this problem, Figure 45 illustrates the use of inverting amplifiers configured with an OP285 to provide a means by which the X- and Y-input offsets can be trimmed.

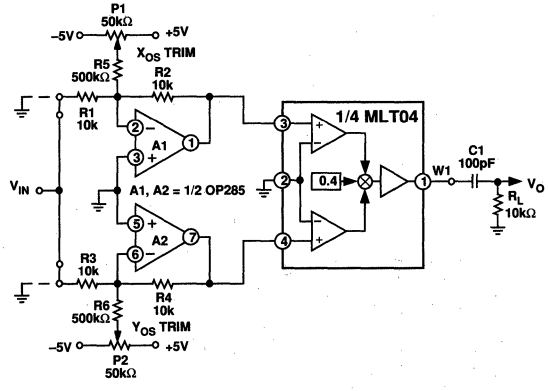

Figure 45. Frequency Doubler with Input Offset Voltage Trims

Feedback Divider Connections

The most commonly used analog divider circuit is the "inverted multiplier" configuration. As illustrated in Figure 46, an "inverted multiplier" analog divider can be configured with a multiplier operating in the feedback loop of an operational amplifier. The general form of the transfer function for this circuit configuration is given by:

$$V_O = -2.5\,V \times \left(\frac{R2}{R1}\right) \times \frac{V_{IN}}{V_X}$$

Here, the multiplier operates as a voltage-controlled potentiometer that adjusts the loop gain of the op amp relative to a control signal, V_X. As the control signal to the multiplier decreases, the output of the multiplier decreases as well. This has the effect of reducing negative feedback which, in turn, decreases the amplifier's loop gain. The result is higher closed-loop gain and reduced circuit bandwidth. As V_X is increased, the output of the multiplier increases which generates more negative feedback — closed-loop gain drops and circuit bandwidth increases. An example of an "inverted multiplier" analog divider frequency response is shown in Figure 47.

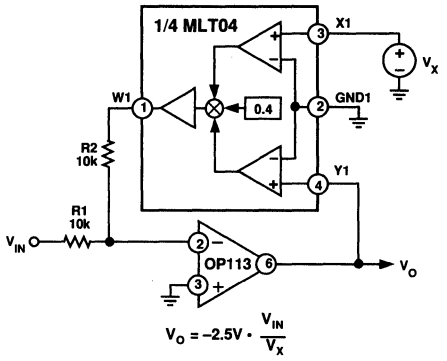

Figure 46. "Inverted-Multiplier" Configuration for Analog Division

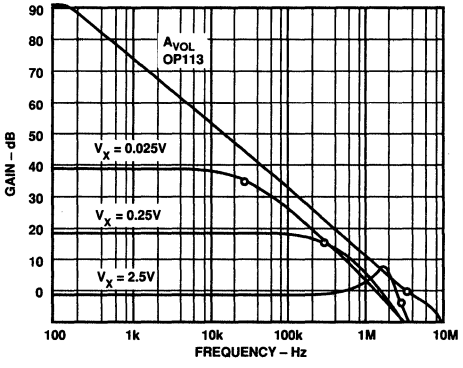

Figure 47. Signal-Dependent Feedback Makes Variables Out of Amplifier Bandwidth and Stability

Although this technique works well with almost any operational amplifier, there is one caveat: for best circuit stability, the unity-gain crossover frequency of the operational amplifier should be equal to or less than the MLT04's 8 MHz bandwidth.

Connection for Square Rooting

Another application of the "inverted multiplier" configuration is the square-root function. As shown in Figure 48, both inputs of the MLT04 are wired together and are used as the output of the circuit. Because the circuit configuration exhibits the following generalized transfer function:

$$V_O = \sqrt{-2.5 \times \left(\frac{R2}{R1}\right) \times V_{IN}}$$

the input signal voltage is limited to the range $-2.5\ V \le V_{IN} < 0$. To prevent circuit latchup due to positive feedback or input signal polarity reversal, a 1N4148-type junction diode is used in series with the output of the multiplier.

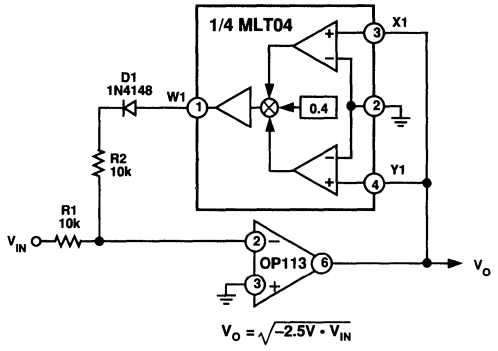

Figure 48. Connections for Square Rooting

Voltage-Controlled Low-Pass Filter

The circuit in Figure 49 illustrates how to construct a voltage-controlled low-pass filter with an analog multiplier. The advantage with this approach over conventional active-filter configurations is that the overall characteristic cut-off frequency, ω_O, will be directly proportional to a multiplying input voltage. This permits the construction of filters in which the capacitors are adjustable (directly or inversely) by a control voltage. Hence, the frequency scale of a filter can be manipulated by means of a single voltage without affecting any other parameters. The general form of the circuit's transfer function is given by:

$$\frac{V_O}{V_{IN}} = -\left(\frac{R2}{R1}\right)\left\{\frac{1}{s\left(\frac{R2+R1}{R1}\right)\left(\frac{2.5RC}{V_X}\right)+1}\right\}$$

In this circuit, the ratio of R2 to R1 sets the passband gain, and the break frequency of the filter, ω_{LP}, is given by:

$$\omega_{LP} = \left(\frac{R1}{R1+R2}\right)\left(\frac{V_X}{2.5RC}\right)$$

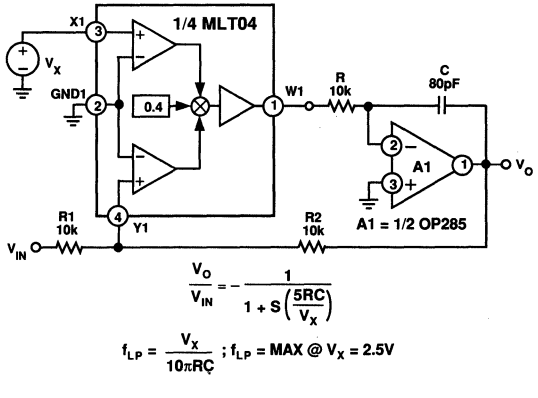

Figure 49. A Voltage-Controlled Low-Pass Filter

Integrated Circuit, True RMS-to-DC Converter

AD536A

FEATURES

True RMS-to-DC Conversion
Laser-Trimmed to High Accuracy
0.2% max Error (AD536AK)
0.5% max Error (AD536AJ)
Wide Response Capability:
Computes RMS of AC and DC Signals
450kHz Bandwidth: V_{rms} > 100mV
2MHz Bandwidth: V_{rms} > 1V
Signal Crest Factor of 7 for 1% Error
dB Output with 60dB Range
Low Power: 1.2mA Quiescent Current
Single or Dual Supply Operation
Monolithic Integrated Circuit
−55°C to +125°C Operation (AD536AS)

PRODUCT DESCRIPTION

The AD536A is a complete monolithic integrated circuit which performs true rms-to-dc conversion. It offers performance which is comparable or superior to that of hybrid or modular units costing much more. The AD536A directly computes the true rms value of any complex input waveform containing ac and dc components. It has a crest factor compensation scheme which allows measurements with 1% error at crest factors up to 7. The wide bandwidth of the device extends the measurement capability to 300kHz with 3dB error for signal levels above 100mV.

An important feature of the AD536A not previously available in rms converters is an auxiliary dB output. The logarithm of the rms output signal is brought out to a separate pin to allow the dB conversion, with a useful dynamic range of 60 dB. Using an externally supplied reference current, the 0dB level can be conveniently set by the user to correspond to any input level from 0.1 to 2 volts rms.

The AD536A is laser trimmed at the wafer level for input and output offset, positive and negative waveform symmetry (dc reversal error), and full-scale accuracy at 7V rms. As a result, no external trims are required to achieve the rated accuracy of the unit.

There is full protection for both inputs and outputs. The input circuitry can take overload voltages well beyond the supply levels. Loss of supply voltage with inputs connected will not cause unit failure. The output is short-circuit protected.

The AD536A is available in two accuracy grades (J, K) for commercial temperature range (0 to +70°C) applications, and one grade (S) rated for the −55°C to +125°C extended range. The AD536AK offers a maximum total error of ±2mV ±0.2% of reading, and the AD536AJ and AD536AS have maximum errors of ±5mV ±0.5% of reading. All three versions are available in either a hermetically sealed 14-pin DIP or 10-pin TO-100 metal can. The AD536AS is also available in a 20-pin hermetically sealed ceramic leadless chip carrier.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

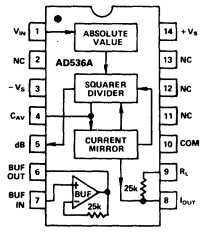
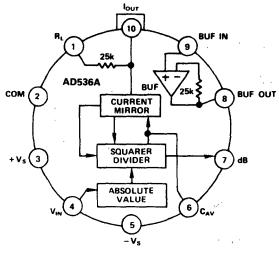
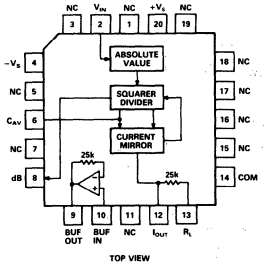
TO-116 (D-14) and Q-14 Packages



TO-100 (H-10A) Package



LCC (E-20A) Package



PRODUCT HIGHLIGHTS

1. The AD536A computes the true root-mean-square level of a complex ac (or ac plus dc) input signal and gives an equivalent dc output level. The true rms value of a waveform is a more useful quantity than the average rectified value since it relates directly to the power of the signal. The rms value of a statistical signal also relates to its standard deviation.
2. The crest factor of a waveform is the ratio of the peak signal swing to the rms value. The crest factor compensation scheme of the AD536A allows measurement of highly complex signals with wide dynamic range.
3. The only external component required to perform measurements to the fully specified accuracy is the capacitor which sets the averaging period. The value of this capacitor determines the low frequency ac accuracy, ripple level and settling time.
4. The AD536A will operate equally well from split supplies or a single supply with total supply levels from 5 to 36 volts. The one milliampere quiescent supply current makes the device well-suited for a wide variety of remote controllers and battery powered instruments.
5. The AD536A directly replaces the AD536 and provides improved bandwidth and temperature drift specifications.

NOTES

[1]Accuracy is specified for 0 to 7V rms, dc or 1kHz sinewave input with the AD536A connected as in the figure referenced.

[2]Error vs. crest factor is specified as an additional error for 1V rms rectangular pulse input, pulse width = 200μs.

[3]Input voltages are expressed in volts rms, and error is percent of reading.

[4]With 2k external pulldown resistor.

Specifications subject to change without notice.

Specifications shown in boldface are tested on all production units at final electrical test. Results from those tests are used to calculate outgoing quality levels. All min and max specifications are guaranteed, although only those shown in boldface are tested on all production units.

STANDARD CONNECTION

The AD536A is simple to connect for the majority of high accuracy rms measurements, requiring only an external capacitor to set the averaging time constant. The standard connection is shown in Figure 1. In this configuration, the AD536A will measure the rms of the ac and dc level present at the input, but will show an error for low frequency inputs as a function of the filter capacitor, C_{AV}, as shown in Figure 5. Thus, if a 4μF capacitor is used, the additional average error at 10Hz will be 0.1%; at 3Hz it will be 1%. The accuracy at higher frequencies will be according to specification. If it is desired to reject the dc input, a capacitor is added in series with the input, as shown in Figure 3, the capacitor must be nonpolar. If the AD536A is driven with power supplies with a considerable amount of high frequency ripple, it is advisable to bypass both supplies to ground with 0.1μF ceramic discs as near the device as possible.

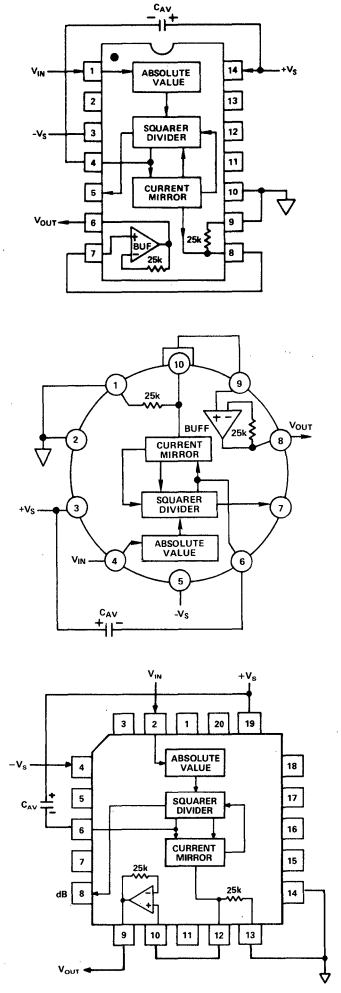

Figure 1. Standard RMS Connection

ANALOG DEVICES

Low Level, True RMS-to-DC Converter

AD636

FEATURES

- True rms-to-dc Conversion
- 200mV Full Scale
- Laser-Trimmed to High Accuracy
  - 0.5% max Error (AD636K)
  - 1.0% max Error (AD636J)
- Wide Response Capability:
  - Computes rms of ac and dc Signals
  - 1MHz -3dB Bandwidth: V_{rms}>100mV
  - Signal Crest Factor of 6 for 0.5% Error
- dB Output with 50dB Range
- Low Power: 800μA Quiescent Current
- Single or Dual Supply Operation
- Monolithic Integrated Circuit
- Low Cost
- Available in Chip Form

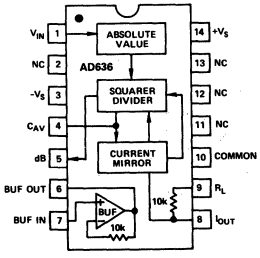
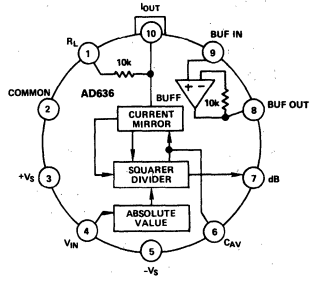
"D" Package (TO-116)



"H" Package (TO-100)



PRODUCT DESCRIPTION

The AD636 is a low power monolithic IC which performs true rms-to-dc conversion on low level signals. It offers performance which is comparable or superior to that of hybrid and modular converters costing much more. The AD636 is specified for a signal range of 0 to 200 millivolts rms. Crest factors up to 6 can be accommodated with less than 0.5% additional error, allowing accurate measurement of complex input waveforms.

The low power supply current requirement of the AD636, typically 800μA, allows it to be used in battery-powered portable instruments. A wide range of power supplies can be used, from ±2.5V to ±16.5V or a single +5V to +24V supply. The input and output terminals are fully protected; the input signal can exceed the power supply with no damage to the device (allowing the presence of input signals in the absence of supply voltage) and the output buffer amplifier is short-circuit protected.

The AD636 includes an auxiliary dB output. This signal is derived from an internal circuit point which represents the logarithm of the rms output. The 0dB reference level is set by an externally supplied current and can be selected by the user to correspond to any input level from 0dBm (774.6mV) to -20dBm (77.46mV). Frequency response ranges from 1.2MHz at a 0dBm level to over 10kHz at -50dBm.

The AD636 is designed for ease of use. The device is factory-trimmed at the wafer level for input and output offset, positive and negative waveform symmetry (dc reversal error), and full scale accuracy at 200mV rms. Thus no external trims are required to achieve full rated accuracy.

AD636 is available in two accuracy grades; the AD636J total error of ±0.5mV ±0.06% of reading, and the AD636K is accurate within ±0.2mV to ±0.03% of reading. Both versions are specified for the 0 to +70°C temperature range, and are offered in either a hermetically sealed 14-pin DIP or a 10-pin TO-100 metal can. Chips are also available.

PRODUCT HIGHLIGHTS

1. The AD636 computes the true root-mean-square of a complex ac (or ac plus dc) input signal and gives an equivalent dc output level. The true rms value of a waveform is a more useful quantity than the average rectified value since it is a measure of the power in the signal. The rms value of an ac-coupled signal is also its standard deviation.
2. The 200 millivolt full scale range of the AD636 is compatible with many popular display-oriented analog-to-digital converters. The low power supply current requirement permits use in battery-powered hand-held instruments.
3. The only external component required to perform measurements to the fully specified accuracy is the averaging capacitor. The value of this capacitor can be selected for the desired trade-off of low frequency accuracy, ripple, and settling time.
4. The on-chip buffer amplifier can be used to buffer either the input or the output. Used as an input buffer, it provides accurate performance from standard 10MΩ input attenuators. As an output buffer, it can supply up to 5 milliamps of output current.
5. The AD636 will operate over a wide range of power supply voltages, including single +5V to +24V or split ±2.5V to ±16.5V sources. A standard 9V battery will provide several hundred hours of continuous operation.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

High Precision, Wideband RMS-to-DC Converter

AD637

FEATURES

High Accuracy
- **0.02% Max Nonlinearity, 0 to 2V RMS Input**
- **0.10% Additional Error to Crest Factor of 3**

Wide Bandwidth
- **8MHz at 1V RMS Input**
- **600kHz at 100mV RMS**

Computes:
- **True RMS**
- **Square**
- **Mean Square**
- **Absolute Value**

dB Output (60dB Range)

Chip Select-Power Down Feature Allows:
- **Analog "3-State" Operation**
- **Quiescent Current Reduction from 2.2mA to 350μA**

Side Brazed DIP, Low-Cost Cerdip and SOIC

PRODUCT DESCRIPTION

The AD637 is a complete high accuracy monolithic rms to dc converter that computes the true rms value of any complex waveform. It offers performance that is unprecedented in integrated circuit rms to dc converters and comparable to discrete and modular techniques in accuracy, bandwidth and dynamic range. A crest factor compensation scheme in the AD637 permits measurements of signals with crest factors of up to 10 with less than 1% additional error. The circuit's wide bandwidth permits the measurement of signals up to 600kHz with inputs of 200mV rms and up to 8MHz when the input levels are above 1V rms.

As with previous monolithic rms converters from Analog Devices, the AD637 has an auxiliary dB output available to the user. The logarithm of the rms output signal is brought out to a separate pin allowing direct dB measurement with a useful range of 60dB. An externally programmed reference current allows the user to select the 0dB reference voltage to correspond to any level between 0.1V and 2.0V rms.

A chip select connection on the AD637 permits the user to decrease the supply current from 2.2mA to 350μA during periods when the rms function is not in use. This feature facilitates the addition of precision rms measurement to remote or hand-held applications where minimum power consumption is critical. In addition when the AD637 is powered down the output goes to a high impedance state. This allows several AD637s to be tied together to form a wide-band true rms multiplexer.

The input circuitry of the AD637 is protected from overload voltages that are in excess of the supply levels. The inputs will not be damaged by input signals if the supply voltages are lost.

The AD637 is available in two accuracy grades (J, K) for commercial (0 to +70°C) temperature range applications; two accuracy grades (A, B) for industrial (−40°C to +85°C) applications; and one (S) rated over the −55°C to +125°C temperature range. All versions are available in hermetically-sealed, 14-pin side-brazed ceramic DIPs as well as low-cost cerdip packages. A 16-pin SOIC package is also available.

PRODUCT HIGHLIGHTS

1. The AD637 computes the true root-mean-square, mean square, or absolute value of any complex ac (or ac plus dc) input waveform and gives an equivalent dc output voltage. The true rms value of a waveform is more useful than an average rectified signal since it relates directly to the power of the signal. The rms value of a statistical signal is also related to the standard deviation of the signal.
2. The AD637 is laser wafer trimmed to achieve rated performance without external trimming. The only external component required is a capacitor which sets the averaging time period. The value of this capacitor also determines low frequency accuracy, ripple level and settling time.
3. The chip select feature of the AD637 permits the user to power down the device down during periods of nonuse, thereby, decreasing battery drain in remote or hand-held applications.
4. The on-chip buffer amplifier can be used as either an input buffer or in an active filter configuration. The filter can be used to reduce the amount of ac ripple, thereby, increasing the accuracy of the measurement.

ANALOG DEVICES

Low Cost, Low Power, True RMS-to-DC Converter

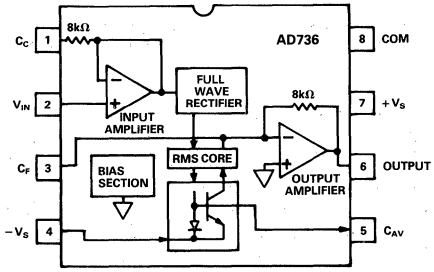
AD736

FEATURES

COMPUTES
- True RMS Value
- Average Rectified Value
- Absolute Value

PROVIDES
- 200mV Full-Scale Input Range (Larger Inputs with Input Attenuator)
- High Input Impedance of $10^{12}\Omega$
- Low Input Bias Current: 25pA max
- High Accuracy: ±0.3mV ±0.3% of Reading
- RMS Conversion with Signal Crest Factors Up to 5
- Wide Power Supply Range: +2.8V, −3.2V to ±16.5V
- Low Power: 200μA max Supply Current
- Buffered Voltage Output
- No External Trims Needed for Specified Accuracy
- AD737 – An Unbuffered Voltage Output Version with Chip Power Down Is Also Available

FUNCTIONAL BLOCK DIAGRAM



PRODUCT DESCRIPTION

The AD736 is a low power, precision, monolithic true rms-to-dc converter. It is laser trimmed to provide a maximum error of ±0.3mV ±0.3% of reading with sine-wave inputs. Furthermore, it maintains high accuracy while measuring a wide range of input waveforms, including variable duty cycle pulses and triac (phase) controlled sine waves. The low cost and small physical size of this converter make it suitable for upgrading the performance of non-rms "precision rectifiers" in many applications. Compared to these circuits, the AD736 offers higher accuracy at equal or lower cost.

The AD736 can compute the rms value of both ac and dc input voltages. It can also be operated ac coupled by adding one external capacitor. In this mode, the AD736 can resolve input signal levels of 100μV rms or less, despite variations in temperature or supply voltage. High acccuracy is also maintained for input waveforms with crest factors of 1 to 3. In addition, crest factors as high as 5 can be measured (while introducing only 2.5% additional error) at the 200mV full-scale input level.

The AD736 has its own output buffer amplifier, thereby providing a great deal of design flexibility. Requiring only 200μA of power supply current, the AD736 is optimized for use in portable multimeters and other battery powered applications.

The AD736 allows the choice of two signal input terminals: a high impedance ($10^{12}\Omega$) FET input which will directly interface with high Z input attenuators and a low impedance (8kΩ) input which allows the measurement of 300mV input levels, while operating from the minimum power supply voltage of +2.8V, −3.2V. The two inputs may be used either singly or differentially.

The AD736 achieves a 1% of reading error bandwidth exceeding 10kHz for input amplitudes from 20mV rms to 200mV rms while consuming only 1mW.

The AD736 is available in four performance grades. The AD736J and AD736K grades are rated over the commercial temperature range of 0 to +70°C. The AD736A and AD736B grades are rated over the industrial temperature range of −40°C to +85°C.

The AD736 is available in three low-cost 8-pin packages: plastic mini-DIP, plastic SO and hermetic cerdip.

PRODUCT HIGHLIGHTS

1. The AD736 is capable of computing the average rectified value, absolute value or true rms value of various input signals.
2. Only one external component, an averaging capacitor, is required for the AD736 to perform true rms measurement.
3. The low power consumption of 1mW makes the AD736 suitable for many battery powered applications.
4. A high input impedance of $10^{12}\Omega$ eliminates the need for an external buffer when interfacing with input attenuators.
5. A low impedance input is available for those applications requiring up to 300mV rms input signal operating from low power supply voltages.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

NOTES
[1]Accuracy is specified with the AD736 connected as shown in Figure 16 with capacitor C_C.
[2]Nonlinearity is defined as the maximum deviation (in percent error) from a straight line connecting the readings at 0 and 200mV rms. Output offset voltage is adjusted to zero.
[3]Error vs. Crest Factor is specified as additional error for a 200mV rms signal. C.F. = V_{PEAK}/V rms.
[4]DC offset does not limit ac resolution.

Specifications are subject to change without notice.
Specifications shown in **boldface** are tested on all production units at final electrical test.
Results from those tests are used to calculate outgoing quality levels.

ANALOG DEVICES

Low Cost, Low Power, True RMS-to-DC Converter

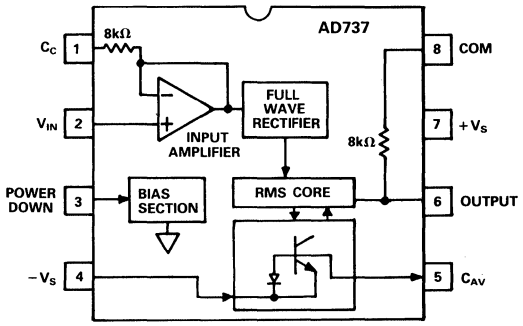
AD737

FEATURES

COMPUTES
- True RMS Value
- Average Rectified Value
- Absolute Value

PROVIDES
- 200mV Full-Scale Input Range (Larger Inputs with Input Attenuator)
- Direct Interfacing with 3 1/2 Digit CMOS A/D Converters
- Power Down Feature Which Reduces Supply Current
- High Input Impedance: 10^{12} Ω
- Low Input Bias Current: 25 pA max
- High Accuracy: ±0.2 mV ±0.3% of Reading
- RMS Conversion with Signal Crest Factors Up to 5
- Wide Power Supply Range: +2.8 V, −3.2 V to ±16.5 V
- Low Power: 160 μA max Supply Current
- No External Trims Needed for Specified Accuracy
- AD736 – A General Purpose, Buffered Voltage Output Version Also Available

FUNCTIONAL BLOCK DIAGRAM



PRODUCT DESCRIPTION

The AD737 is a low power, precision, monolithic true rms-to-dc converter. It is laser trimmed to provide a maximum error of ±0.2 mV ±0.3% of reading with sine wave inputs. Furthermore, it maintains high accuracy while measuring a wide range of input waveforms, including variable duty cycle pulses and triac (phase) controlled sine waves. The low cost and small physical size of this converter make it suitable for upgrading the performance of non-rms "precision rectifiers" in many applications. Compared to these circuits, the AD737 offers higher accuracy at equal or lower cost.

The AD737 can compute the rms value of both ac and dc input voltages. It can also be operated ac coupled by adding one external capacitor. In this mode, the AD737 can resolve input signal levels of 100 μV rms or less, despite variations in temperature or supply voltage. High accuracy is also maintained for input waveforms with crest factors of 1 to 3. In addition, crest factors as high as 5 can be measured (while introducing only 2.5% additional error) at the 200 mV full-scale input level.

The AD737 has no output buffer amplifier, thereby significantly reducing dc offset errors occurring at the output. This allows the device to be highly compatible with high input impedance A/D converters.

Requiring only 160 μA of power supply current, the AD737 is optimized for use in portable multimeters and other battery powered applications. This converter also provides a "power down" feature which reduces the power supply standby current to less than 30 μA.

The AD737 allows the choice of two signal input terminals: a high impedance (10^{12} Ω) FET input which will directly interface with high Z input attenuators and a low impedance (8 kΩ) input which allows the measurement of 300 mV input levels while operating from the minimum power supply voltage of +2.8 V, −3.2 V. The two inputs may be used either singly or differentially.

The AD737 achieves a 1% of reading error bandwidth exceeding 10 kHz for input amplitudes from 20 mV rms to 200 mV rms while consuming only 0.72 mW.

The AD737 is available in four performance grades. The AD737J and AD737K grades are rated over the commercial temperature range of 0 to +70°C. The AD737A and AD737B grades are rated over the industrial temperature range of −40°C to +85°C.

The AD737 is available in three low cost, 8-pin packages: plastic mini-DIP, plastic SO and hermetic cerdip.

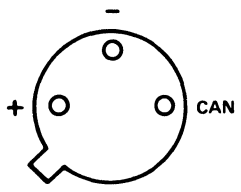
ANALOG DEVICES

Two-Terminal IC Temperature Transducer

AD590*

FEATURES
Linear Current Output: 1μA/K
Wide Range: -55°C to +150°C
Probe Compatible Ceramic Sensor Package
Two-Terminal Device: Voltage In/Current Out
Laser Trimmed to ±0.5°C Calibration Accuracy (AD590M)
Excellent Linearity: ±0.3°C Over Full Range (AD590M)
Wide Power Supply Range: +4V to +30V
Sensor Isolation from Case
Low Cost

PIN DESIGNATIONS



BOTTOM VIEW

PRODUCT DESCRIPTION

The AD590 is a two-terminal integrated circuit temperature transducer which produces an output current proportional to absolute temperature. For supply voltages between +4V and +30V the device acts as a high impedance, constant current regulator passing 1μA/K. Laser trimming of the chip's thin film resistors is used to calibrate the device to 298.2μA output at 298.2K (+25°C).

The AD590 should be used in any temperature sensing application below +150°C in which conventional electrical temperature sensors are currently employed. The inherent low cost of a monolithic integrated circuit combined with the elimination of support circuitry makes the AD590 an attractive alternative for many temperature measurement situations. Linearization circuitry, precision voltage amplifiers, resistance measuring circuitry and cold junction compensation are not needed in applying the AD590.

In addition to temperature measurement, applications include temperature compensation or correction of discrete components, biasing proportional to absolute temperature, flow rate measurement, level detection of fluids and anemometry. The AD590 is available in chip form making it suitable for hybrid circuits and fast temperature measurements in protected environments.

The AD590 is particularly useful in remote sensing applications. The device is insensitive to voltage drops over long lines due to its high impedance current output. Any well-insulated twisted pair is sufficient for operation hundreds of feet from the receiving circuitry. The output characteristics also make the AD590 easy to multiplex: the current can be switched by a CMOS multiplexer or the supply voltage can be switched by a logic gate output.

***Covered by Patent No. 4,123,698.**

PRODUCT HIGHLIGHTS

1. The AD590 is a calibrated two terminal temperature sensor requiring only a dc voltage supply (+4V to +30V). Costly transmitters, filters, lead wire compensation and linearization circuits are all unnecessary in applying the device.
2. State-of-the-art laser trimming at the wafer level in conjunction with extensive final testing insures that AD590 units are easily interchangeable.
3. Superior interference rejection results from the output being a current rather than a voltage. In addition, power requirements are low (1.5mW's @ 5V @ +25°C). These features make the AD590 easy to apply as a remote sensor.
4. The high output impedance (>10MΩ) provides excellent rejection of supply voltage drift and ripple. For instance, changing the power supply from 5V to 10V results in only a 1μA maximum current change, or 1°C equivalent error.
5. The AD590 is electrically durable: it will withstand a forward voltage up to 44V and a reverse voltage of 20V. Hence, supply irregularities or pin reversal will not damage the device.

TEMPERATURE SCALE CONVERSION EQUATIONS

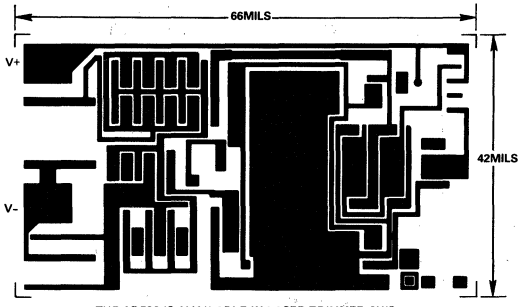
$$°C = \frac{5}{9}(°F - 32) \qquad K = °C + 273.15$$

$$°F = \frac{9}{5}°C + 32 \qquad °R = °F + 459.7$$

The 590H has 60μ inches of gold plating on its Kovar leads and Kovar header. A resistance welder is used to seal the nickel cap to the header. The AD590 chip is eutectically mounted to the header and ultrasonically bonded to with 1 MIL aluminum wire. Kovar composition: 53% iron nominal; 29% ±1% nickel; 17% ±1% cobalt; 0.65% manganese max; 0.20% silicon max; 0.10% aluminum max; 0.10% magnesium max; 0.10% zirconium max; 0.10% titanium max; 0.06% carbon max.

The 590F is a ceramic package with gold plating on its Kovar leads, Kovar lid, and chip cavity. Solder of 80/20 Au/Sn composition is used for the 1.5 mil thick solder ring under the lid. The chip cavity has a nickel underlay between the metalization and the gold plating. The AD590 chip is eutectically mounted in the chip cavity at 410°C and ultrasonically bonded to with 1 mil aluminum wire. Note that the chip is in direct contact with the ceramic base, not the metal lid. When using the AD590 in die form, the chip substrate must be kept electrically isolated, (floating), for correct circuit operation.

METALIZATION DIAGRAM



THE AD590 IS AVAILABLE IN LASER-TRIMMED CHIP FORM; CONSULT THE CHIP CATALOG FOR DETAILS.

CIRCUIT DESCRIPTION[1]

The AD590 uses a fundamental property of the silicon transistors from which it is made to realize its temperature proportional characteristic: if two identical transistors are operated at a constant ratio of collector current densities, r, then the difference in their base-emitter voltages will be (kT/q)(In r). Since both k, Boltzman's constant and q, the charge of an electron, are constant, the resulting voltage is directly porportional to absolute temperature (PTAT).

In the AD590, this PTAT voltage is converted to a PTAT current by low temperature coefficient thin film resistors. The total current of the device is then forced to be a multiple of this PTAT current. Referring to Figure 1, the schematic diagram of the AD590, Q8 and Q11 are the transistors that produce the PTAT voltage. R5 and R6 convert the voltage to current. Q10, whose collector current tracks the collector currents in Q9 and Q11, supplies all the bias and substrate leakage current for the rest of the circuit, forcing the total current to be PTAT. R5 and R6 are laser trimmed on the wafer to calibrate the device at +25°C.

Figure 2 shows the typical V–I characteristic of the circuit at +25°C and the temperature extremes.

ANALOG DEVICES

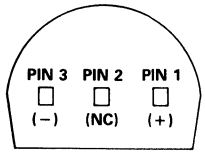
Low Cost, Precision IC Temperature Transducer

AD592*

FEATURES

High Precalibrated Accuracy: 0.5°C max @ 25°C
Excellent Linearity: 0.15°C max (0 to +70°C)
Wide Operating Temperature Range: −25°C to +105°C
Single Supply Operation: +4V to +30V
Excellent Repeatability and Stability
High Level Output: 1μA/K
Two Terminal Monolithic IC: Temperature In/ Current Out
Minimal Self-Heating Errors

CONNECTION DIAGRAM



*PIN 2 CAN BE EITHER ATTACHED OR UNCONNECTED

BOTTOM VIEW

PRODUCT DESCRIPTION

The AD592 is a two terminal monolithic integrated circuit temperature transducer that provides an output current proportional to absolute temperature. For a wide range of supply voltages the transducer acts as a high impedance temperature dependent current source of 1μA/K. Improved design and laser wafer trimming of the IC's thin film resistors allows the AD592 to achieve absolute accuracy levels and nonlinearity errors previously unattainable at a comparable price.

The AD592 can be employed in applications between −25°C and +105°C where conventional temperature sensors (i.e., thermistor, RTD, thermocouple, diode) are currently being used. The inherent low cost of a monolithic integrated circuit in a plastic package, combined with a low total parts count in any given application, make the AD592 the most cost effective temperature transducer currently available. Expensive linearization circuitry, precision voltage references, bridge components, resistance measuring circuitry and cold junction compensation are not required with the AD592.

Typical application areas include; appliance temperature sensing, automotive temperature measurement and control, HVAC (heating/ventilating/air conditioning) system monitoring, industrial temperature control, thermocouple cold junction compensation, board-level electronics temperature diagnostics, temperature readout options in instrumentation, and temperature correction circuitry for precision electronics. Particularly useful in remote sensing applications, the AD592 is immune to voltage drops and voltage noise over long lines due to its high impedance current output. AD592s can easily be multiplexed; the signal current can be switched by a CMOS multiplexer or the supply voltage can be enabled with a tri-state logic gate.

The AD592 is available in three performance grades; the AD592AN, AD592BN and AD592CN. All devices are packaged in a plastic TO-92 case rated from −45°C to +125°C. Performance is specified from −25°C to +105°C. AD592 chips are also available, contact the factory for details.

PRODUCT HIGHLIGHTS

1. With a single supply (4V to 30V) the AD592 offers 0.5°C temperature measurement accuracy.
2. A wide operating temperature range (−25°C to +105°C) and highly linear output make the AD592 an ideal substitute for older, more limited sensor technologies (i.e., thermistors, RTDs, diodes, thermocouples).
3. The AD592 is electrically rugged; supply irregularities and variations or reverse voltages up to 20V will not damage the device.
4. Because the AD592 is a temperature dependent current source, it is immune to voltage noise pickup and IR drops in the signal leads when used remotely.
5. The high output impedance of the AD592 provides greater than 0.5°C/V rejection of supply voltage drift and ripple.
6. Laser wafer trimming and temperature testing insures that AD592 units are easily interchangeable.
7. Initial system accuracy will not degrade significantly over time. The AD592 has proven long term performance and repeatability advantages inherent in integrated circuit design and construction.

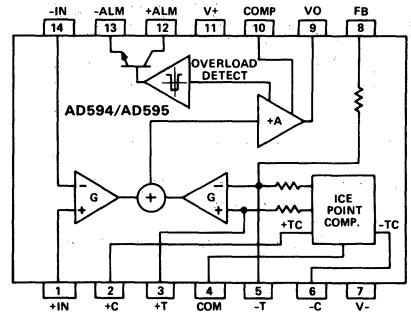
Monolithic Thermocouple Amplifiers with Cold Junction Compensation

AD594*/AD595*

FEATURES

Pretrimmed for Type J (AD594) or Type K (AD595) Thermocouples
Can Be Used with Type T Thermocouple Inputs
Low Impedance Voltage Output: 10mV/°C
Built-in Ice Point Compensation
Wide Power Supply Range: +5V to ±15V
Low Power: <1mW typical
Thermocouple Failure Alarm
Laser Wafer Trimmed to 1°C Calibration Accuracy
Set-Point Mode Operation
Self-Contained Celsius Thermometer Operation
High Impedance Differential Input
Side-Brazed DIP or Low Cost Cerdip

FUNCTIONAL BLOCK DIAGRAM



PRODUCT DESCRIPTION

The AD594/AD595 is a complete instrumentation amplifier and thermocouple cold junction compensator on a monolithic chip. It combines an ice point reference with a precalibrated amplifier to produce a high level (10mV/°C) output directly from a thermocouple signal. Pin-strapping options allow it to be used as a linear amplifier-compensator or as a switched output set-point controller using either fixed or remote set-point control. It can be used to amplify its compensation voltage directly, thereby converting it to a stand-alone Celsius transducer with a low-impedance voltage output.

The AD594/AD595 includes a thermocouple failure alarm that indicates if one or both thermocouple leads become open. The alarm output has a flexible format which includes TTL drive capability.

The AD594/AD595 can be powered from a single ended supply (including +5V) and by including a negative supply, temperatures below 0°C can be measured. To minimize self-heating, an unloaded AD594/AD595 will typically operate with a total supply current of 160μA, but is also capable of delivering in excess of ±5mA to a load.

The AD594 is precalibrated by laser wafer trimming to match the characteristic of type J (iron-constantan) thermocouples and the AD595 is laser trimmed for type K (chromel-alumel) inputs. The temperature transducer voltages and gain control resistors are available at the package pins so that the circuit can be recalibrated for other thermocouple types by the addition of two or three resistors. These terminals also allow more precise calibration for both thermocouple and thermometer applications.

***Protected by U.S. Patent No. 4,029,974.**

The AD594/AD595 is available in two performance grades. The C and the A versions have calibration accuracies of ±1°C and ±3°C, respectively. Both are designed to be used from 0 to +50°C, and are available in 14-pin, hermetically sealed, side-brazed ceramic DIPs as well as low cost cerdip packages.

PRODUCT HIGHLIGHTS

1. The AD594/AD595 provides cold junction compensation, amplification, and an output buffer in a single IC package.
2. Compensation, zero, and scale factor are all precalibrated by laser wafer trimming (LWT) of each IC chip.
3. Flexible pin-out provides for operation as a set-point controller or a stand-alone temperature transducer calibrated in degrees Celsius.
4. Operation at remote application sites is facilitated by low quiescent current and a wide supply voltage range of +5V to dual supplies spanning 30V.
5. Differential input rejects common-mode noise voltage on the thermocouple leads.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

NOTES

[1]Calibrated for minimum error at +25°C using a thermocouple sensitivity of 51.7 µV/°C. Since a J type thermocouple deviates from this straight line approximation, the AD594 will normally read 3.1 mV when the measuring junction is at 0°C. The AD595 will similarly read 2.7 mV at 0°C.

[2]Defined as the slope of the line connecting the AD594/AD595 errors measured at 0°C and 50°C ambient temperature.

[3]Pin 8 shorted to Pin 9.

[4]Current Sink Capability in single supply configuration is limited to current drawn to ground through a 50 kΩ resistor at output voltages below 2.5 V.

[5]$-V_S$ must not exceed −16.5 V.

[6]For outline information see Package Information section.

Specifications subject to change without notice.

Specifications shown in **boldface** are tested on all production units at final electrical test. Results from those tests are used to calculate outgoing quality levels.
All min and max specifications are guaranteed, although only those shown in boldface are tested on all production units.

Table I. Output Voltage vs. Thermocouple Temperature (Ambient +25°C, V_S = −5V, +15V)

INTERPRETING AD594/AD595 OUTPUT VOLTAGES

To achieve a temperature proportional output of 10mV/°C and accurately compensate for the reference junction over the rated operating range of the circuit, the AD594/AD595 is gain trimmed to match the transfer characteristic of J and K type thermocouples at 25°C. For a type J output in this temperature range the TC is 51.70μV/°C, while for a type K it is 40.44μV/°C. The resulting gain for the AD594 is 193.4 (10mV/°C divided by 51.7μV/°C) and for the AD595 is 247.3 (10mV/°C divided by 40.44μV/°C). In addition, an absolute accuracy trim induces an input offset to the output amplifier characteristic of 16μV for the AD594 and 11μV for the AD595. This offset arises because the AD594/AD595 is trimmed for a 250mV output while applying a 25°C thermocouple input.

Because a thermocouple output voltage is nonlinear with respect to temperature, and the AD594/AD595 linearly amplifies the compensated signal, the following transfer functions should be used to determine the actual output voltages:

AD594 output = (Type J Voltage + 16μV) × 193.4

AD595 output = (Type K Voltage + 11μV) × 247.3

or conversely:

Type J voltage = (AD594 output / 193.4) − 16μV

Type K voltage = (AD595 output / 247.3) − 11μV

Table I above lists the ideal AD594/AD595 output voltages as a function of Celsius temperature for type J and K ANSI standard thermocouples, with the package and reference junction at 25°C. As is normally the case, these outputs are subject to calibration, gain and temperature sensitivity errors. Output values for intermediate temperatures can be interpolated, or calculated using the output equations and ANSI thermocouple voltage tables referred to zero degrees Celsius. Due to a slight variation in alloy content between ANSI type J and DIN Fe–CuNi thermocouples Table I should not be used in conjunction with European standard thermocouples. Instead the transfer function given previously and a DIN thermocouple table should be used. ANSI type K and DIN NiCr–Ni thermocouples are composed of identical alloys and exhibit similar behavior. The upper temperature limits in Table I are those recommended for type J and type K thermocouples by the majority of vendors.

ANALOG DEVICES

Thermocouple Conditioner and Set-Point Controller

AD596*/AD597*

FEATURES
Low Cost
Operates with Type J (AD596) or Type K (AD597) Thermocouples
Built-in Ice Point Compensation
Temperature Proportional Operation – 10mV/°C
Temperature Set-Point Operation – ON/OFF
Programmable Switching Hysteresis
High Impedance Differential Input

PRODUCT DESCRIPTION

The AD596/AD597 is a monolithic temperature set-point controller which has been optimized for use at elevated temperatures such as those found in oven control applications. The device cold junction compensates and amplifies a type J or K thermocouple input to derive an internal signal proportional to temperature. The internal signal is then compared with an externally applied set-point voltage to yield a low impedance switched output voltage. Dead-Band or switching hysteresis can be programmed using a single external resistor. Alternately, the AD596/AD597 can be configured to provide a voltage output (10mV/°C) directly from a type J or K thermocouple signal. It can also be used as a stand-alone voltage output temperature sensor.

The AD596/AD597 can be powered with a single supply from +5V to +30V, or dual supplies up to a total span of 36V. Typical quiescent supply current is 160μA which minimizes self-heating errors.

The AD596/AD597 H package option includes a thermocouple failure alarm that indicates an open thermocouple lead when operated in the temperature proportional measurement mode. The alarm output has a flexible format which can be used to drive relays, LEDs or TTL logic.

The device is packaged in a reliability qualified, cost effective 10-pin metal can, 8-pin plastic minidip or SOIC and is trimmed to operate over an ambient temperature range from +25°C to +100°C. Operation over an extended ambient temperature range is possible with slightly reduced accuracy. The AD596 will amplify thermocouple signals covering the entire −200°C to +760°C temperature range recommended for type J thermocouples while the AD597 can accommodate −200°C to +1250°C type K inputs.

The AD596/AD597 has a calibration accuracy of ±4°C at an ambient temperature of 60°C and an ambient temperature stability specification of 0.05°C/°C from +25°C to +100°C. If higher accuracy, or a lower ambient operating temperature is required, either the AD594 (J thermocouple) or AD595 (K thermocouple) should be considered.

PRODUCT HIGHLIGHTS

1. The AD596/AD597 provides cold junction compensation and a high gain amplifier which can be used as a set-point comparator.
2. The input stage of the AD596/AD597 is a high quality instrumentation amplifier that allows the thermocouple to float over most of the supply voltage range.
3. Linearization not required for thermocouple temperatures close to 175°C (+100°C to +540°C for AD596).
4. Cold junction compensation is optimized for ambient temperatures ranging from +25°C to +100°C.
5. In the stand-alone mode, the AD596/AD597 produces an output voltage that indicates its own temperature.

NOTES

[1]This is a measure of the deviation from ideal with a measuring thermocouple junction of 175°C and a chip temperature of 60°C. The ideal transfer function is given by:

AD596: $V_{OUT} = 180.57\times(V_m-V_a+$ (ambient in °C)$\times 53.21\mu V/°C +235\mu V)$

AD597: $V_{OUT} = 245.46\times(V_m-V_a+$ (ambient in °C)$\times 41.27\mu V/°C -37\mu V)$

where V_m and V_a represent the measuring and ambient temperatures and are taken from the appropriate J or K thermocouple table. The ideal transfer function minimizes the error over the ambient temperature range of 25°C to 100°C with a thermocouple temperature of approximately 175°C.

[2]Defined as the slope of the line connecting the AD596/AD597 CJC errors measured at 25°C and 100°C ambient temperature.

[3]Pin 6 shorted to pin 7.

[4]Current Sink Capability in single supply configuration is limited to current drawn to ground through a 50kΩ resistor at output voltages below 2.5V.

[5]Alarm function available on H package option only.

Specifications subject to change without notice.

Specifications shown in boldface are tested on all production units at final electrical test. Results from those tests are used to calculate outgoing quality levels. All min and max specifications are guaranteed, although only those shown in boldface are tested on all production units.

Table I. Output Voltage vs. Thermocouple Temperature (Ambient +60°C, V_S = −5V, +15V)

TEMPERATURE PROPORTIONAL OUTPUT MODE

The AD596/AD597 can be used to generate a temperature proportional output of 10mV/°C when operated with J and K type thermocouples as shown in Figure 1. Thermocouples produce low level output voltages which are a function of both the temperature being measured and the reference or cold junction temperature. The AD596/AD597 compensates for the cold junction temperature and amplifies the thermocouple signal to produce a high level 10mV/°C voltage output which is a function only of the temperature being measured. The temperature stability of the part indicates the sensitivity of the output voltage to changes in ambient or device temperatures. This is typically 0.02°C/°C over the +25°C to +100°C recommended ambient temperature range. The parts will operate over the extended ambient temperature ranges from −55°C to +125°C, but thermocouple nonlinearity at the reference junction will degrade the temperature stability over this extended range. Table I is a list of ideal AD596/AD597 output voltages as a function of Celsius temperature for type J and K ANSI standard thermocouples with package and reference junction at 60°C. As is normally the case, these outputs

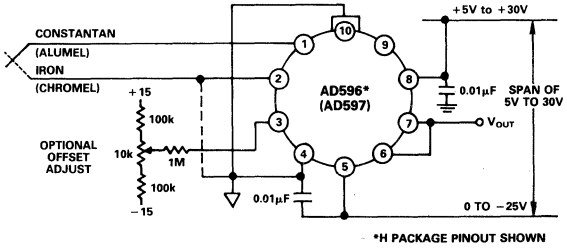

Figure 1. Temperature Proportional Output Connection

are subject to calibration and temperature sensitivity errors. These tables are derived using the ideal transfer functions:

AD596 output = (Type J voltage +301.5µV) × 180.57
AD597 output = (Type K voltage) × 245.46

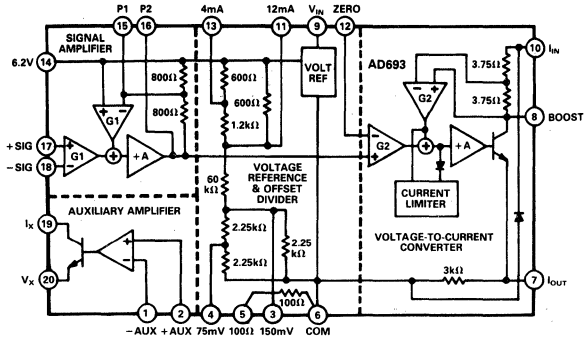
Loop-Powered 4–20mA Sensor Transmitter

AD693

FEATURES

- **Instrumentation Amplifier Front End**
- **Loop-Powered Operation**
- **Precalibrated 30mV or 60mV Input Spans**
- **Independently Adjustable Output Span and Zero**
- **Precalibrated Output Spans: 4–20mA Unipolar**
  0–20mA Unipolar
  12 ± 8mA Bipolar
- **Precalibrated 100Ω RTD Interface**
- **6.2V Reference with Up to 3.5mA of Current Available**
- **Uncommitted Auxiliary Amp for Extra Flexibility**
- **Optional External Pass Transistor to Reduce Self-Heating Errors**

FUNCTIONAL BLOCK DIAGRAM



PRODUCT DESCRIPTION

The AD693 is a monolithic signal conditioning circuit which accepts low-level inputs from a variety of transducers to control a standard 4–20mA, two-wire current loop. An on-chip voltage reference and auxiliary amplifier are provided for transducer excitation; up to 3.5mA of excitation current is available when the device is operated in the loop-powered mode. Alternatively, the device may be locally powered for three-wire applications when 0–20mA operation is desired.

Precalibrated 30mV and 60mV input spans may be set by simple pin strapping. Other spans from 1mV to 100mV may be realized with the addition of external resistors. The auxiliary amplifier may be used in combination with on-chip voltages to provide six precalibrated ranges for 100Ω RTDs. Output span and zero are also determined by pin strapping to obtain the standard ranges: 4–20mA, 12 ± 8mA and 0–20mA.

Active laser trimming of the AD693's thin-film resistors result in high levels of accuracy without the need for additional adjustments and calibration. Total unadjusted error is tested on every device to be less than 0.5% of full scale at +25°C, and less than 0.75% over the industrial temperature range. Residual nonlinearity is under 0.05%. The AD693 also allows for the use of an external pass transistor to further reduce errors caused by self-heating.

For transmission of low-level signals from RTDs, bridges and pressure transducers, the AD693 offers a cost-effective signal conditioning solution. It is recommended as a replacement for discrete designs in a variety of applications in process control, factory automation and system monitoring.

The AD693 is packaged in a 20-pin ceramic side-brazed DIP, 20-pin Cerdip, and 20-pin LCCC and is specified over the −40°C to +85°C industrial temperature range.

PRODUCT HIGHLIGHTS

1. The AD693 is a complete monolithic low-level voltage-to-current loop signal conditioner.
2. Precalibrated output zero and span options include 4–20mA, 0–20mA, and 12 ± 8mA in two- and three-wire configurations.
3. Simple resistor programming adds a continuum of ranges to the basic 30mV and 60mV input spans.
4. The common-mode range of the signal amplifier input extends from ground to near the device's operating voltage.
5. Provision for transducer excitation includes a 6.2V reference output and an auxiliary amplifier which may be configured for voltage or current output and signal amplification.
6. The circuit configuration permits simple linearization of bridge, RTD, and other transducer signals.
7. A monitored output is provided to drive an external pass transistor. This feature off-loads power dissipation to extend the temperature range of operation, enhance reliability, and minimize self-heating errors.
8. Laser-wafer trimming results in low unadjusted errors and affords precalibrated input and output spans.
9. Zero and span are independently adjustable and noninteractive to accommodate transducers or user defined ranges.
10. Six precalibrated temperature ranges are available with a 100Ω RTD via pin strapping.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

NOTES

[1]Total error can be significantly reduced (typically less than 0.1%) by trimming the zero current. The remaining unadjusted error sources are transconductance and nonlinearity.

[2]The AD693 is tested as a loop powered device with the signal amp, V/I converter, voltage reference, and application voltages operating together. Specifications are valid for preset spans and spans between 30mV and 60mV.

[3]Error from ideal output assuming a perfect 100Ω RTD at 0 and +100°C.

[4]Refer to the Error Analysis to calculate zero current error for input spans less than 30mV.

[5]By forcing the differential signal amplifier input sufficiently negative the 7μA zero current can always be achieved.

[6]The operational voltage (V_{OP}) is the voltage directly across the AD693 (Pin 10 to 6 in two-wire mode, Pin 9 to 6 in local power mode). For example, $V_{OP} = V_S - (I_{LOOP} \times R_L)$ in two-wire mode (refer to Figure 10).

[7]Bias currents are not symmetrical with input signal level and flow out of the input pins. The input bias current of the inverting input increases with input signal voltage, see Figure 2.

[8]Nonlinearity is defined as the deviation of the output from a straight line connecting the endpoints as the input is swept over a 30mV and 60mV input span.

[9]Specifications for the individual functional blocks are components of error that contribute to, and that are included in, the Loop Powered Operation specifications.

[10]Includes error contributions of V/I converter and Application Voltages.

[11]Changes in the reference output voltage due to load will affect the Zero Current. A 1% change in the voltage reference output will result in an error of 1% in the value of the Zero Current.

[12]If not used for external excitation, the reference should be loaded by approximately 1mA (6.2kΩ to common).

[13]In the loop powered mode up to 5mA can be drawn from the reference, however, the lower limit of the output span will be increased accordingly. 3.5mA is the maximum current the reference can source while still maintaining a 4mA zero.

[14]The AD693 is tested with a pass transistor so $T_A \cong T_C$.

Specifications subject to change without notice.

Specifications shown in **boldface** are tested on all production units at final electrical test. Results from those tests are used to calculate outgoing quality levels. All min and max specifications are guaranteed, although only those shown in boldface are tested on all production units.

FUNCTIONAL DESCRIPTION

The operation of the AD693 can be understood by dividing the circuit into three functional parts (see Figure 9). First, an instrumentation amplifier front-end buffers and scales the low-level input signal. This amplifier drives the second section, a V/I converter, which provides the 4–to–20mA loop current. The third section, a voltage reference and resistance divider, provides application voltages for setting the various "live zero" currents. In addition to these three main sections, there is an on-chip auxiliary amplifier which can be used for transducer excitation.

VOLTAGE-TO-CURRENT (V/I) CONVERTER

The output NPN transistor for the V/I section sinks loop current when driven on by a high gain amplifier at its base. The input for this amplifier is derived from the difference in the outputs of the matched preamplifiers having gains, G2. This difference is caused to be small by the large gain, +A, and the negative feedback through the NPN transistor and the loop current sampling resistor between I_{IN} and Boost. The signal across this resistor is compared to the input of the left preamp and servos the loop current until both signals are equal. Accurate voltage-to-current transformation is thereby assured. The preamplifiers employ a special design which allows the active feedback amplifier to operate from the most positive point in the circuit, I_{IN}.

The V/I stage is designed to have a nominal transconductance of 0.2666 A/V. Thus, a 75mV signal applied to the inputs of the V/I (Pin 16, noninverting; Pin 12, inverting) results in a full-scale output current of 20mA.

The current limiter operates as follows: the output of the feedback preamp is an accurate indication of the loop current. This output is compared to an internal setpoint which backs off the drive to the NPN transistor when the loop current approaches 25mA. As a result, the loop and the AD693 are protected from the consequences of voltage overdrive at the V/I input.

VOLTAGE REFERENCE AND DIVIDER

A stabilized bandgap voltage reference and laser-trimmed resistor divider provide for both transducer excitation as well as precalibrated offsets for the V/I converter. When not used for external excitation, the reference should be loaded by approximately 1mA (6.2kΩ to common).

The 4mA and 12mA taps on the resistor divider correspond to −15mV and −45mV, respectively, and result in a live zero of 4mA or 12mA of loop current when connected to the V/I converter's inverting input (Pin 12). Arranging the zero offset in this way makes the zero signal output current independent of input span. When the input to the signal amp is zero, the noninverting input of the V/I is at 6.2V.

Since the standard offsets are laser trimmed at the factory, adjustment is seldom necessary except to accommodate the zero offset of the actual source. (See "Adjusting Zero".)

SIGNAL AMPLIFIER

The Signal Amplifier is an instrumentation amplifier used to buffer and scale the input to match the desired span. Inputs applied to the Signal Amplifier (at Pins 17 and 18) are amplified and referred to the 6.2V reference output in much the same way as the level translation occurs in the V/I converter. Signals from the two preamplifiers are subtracted, the difference is amplified, and the result is fed back to the upper preamp to minimize the difference. Since the two preamps are identical, this minimum will occur when the voltage at the upper preamp just matches the differential input applied to the Signal Amplifier at the left.

Since the signal which is applied to the V/I is attenuated across the two 800Ω resistors before driving the upper preamp, it will necessarily be an amplified version of the signal applied between Pins 17 and 18. By changing this attenuation, you can control the span referred to the Signal Amplifier. To illustrate: a 75mV signal applied to the V/I results in a 20mA loop current. Nominally, 15mV is applied to offset the zero to 4mA leaving a 60mV range to correspond to the span. And, since the nominal attenuation of the resistors connected to Pins 16, 15 and 14 is 2.00, a 30mV input signal will be doubled to result in 20mA of loop current. Shorting Pins 15 and 16 results in unity gain and permits a 60mV input span. Other choices of span may be implemented with user supplied resistors to modify the attenuation. (See section "Adjusting Input Span".)

The Signal Amplifier is specially designed to accommodate a large common-mode range. Common-mode signals anywhere up to and beyond the 6.2V reference are easily handled as long as V_{IN} is sufficiently positive. The Signal Amplifier is biased with respect to V_{IN} and requires about 3.5 volts of headroom. The extended range will be useful when measuring sensors driven, for example, by the auxiliary amplifier which may go above the 6.2V potential. In addition, the PNP input stage will continue to operate normally with common-mode voltages of several hundred mV, negative, with respect to common. This feature accommodates self-generating sensors, such as thermocouples,

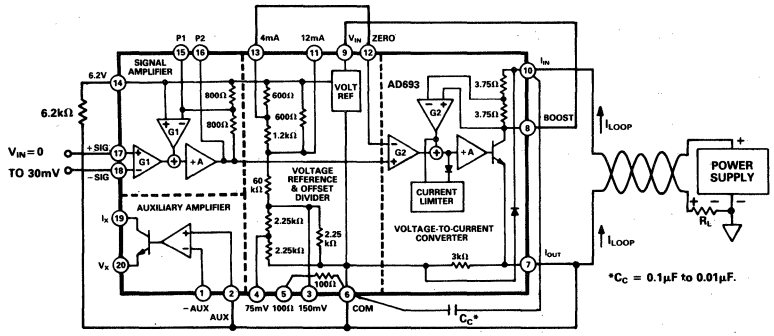

Figure 9. Minimal Connection for 0-30mV Unipolar Input, 4-20mA Output

which may produce small negative normal-mode signals as well as common-mode noise on "grounded" signal sources.

AUXILIARY AMPLIFIER

The Auxiliary Amplifier is included in the AD693 as a signal conditioning aid. It can be used as an op amp in noninverting applications and has special provisions to provide a controlled current output. Designed with a differential input stage and an unbiased Class A output stage, the amplifier can be resistively loaded to common with the self-contained 100Ω resistor or with a user supplied resistor.

As a functional element, the Auxiliary Amplifier can be used in dynamic bridges and arrangements such as the RTD signal conditioner shown in Figure 17. It can be used to buffer, amplify and combine other signals with the main Signal Amplifier. The Auxiliary Amplifier can also provide other voltages for excitation if the 6.2V of the reference is unsuitable. Configured as a simple follower, it can be driven from a user supplied voltage divider or the precalibrated outputs of the AD693 divider (Pins 3 and 4) to provide a stiff voltage output at less than the 6.2 level, or by incorporating a voltage divider as feedback around the amplifier, one can gain-up the reference to levels higher than 6.2V. If large positive outputs are desired, I_X, the Auxiliary Amplifier output current supply, should be strapped to either V_{IN} or Boost. Like the Signal Amplifier, the Auxiliary requires about 3.5V of headroom with respect to V_{IN} at its input and about 2V of difference between I_X and the voltage to which V_X is required to swing.

The output stage of the Auxiliary Amplifier is actually a high gain Darlington transistor where I_X is the collector and V_X is the emitter. Thus, the Auxiliary Amplifier can be used as a V/I converter when configured as a follower and resistively loaded. I_X functions as a high-impedance current source whose current is equal to the voltage at V_X divided by the load resistance. For example, using the onboard 100Ω resistor and the 75mV or 150mV application voltages, either a 750μA or 1.5mA current source can be set up for transducer excitation.

The I_X terminal has voltage compliance within 2V of V_X. If the Auxiliary Amplifier is not to be used, then Pin 2, the noninverting input, should be grounded.

REVERSE VOLTAGE PROTECTION FEATURE

In the event of a reverse voltage being applied to the AD693 through a current-limited loop (limited to 200mA), an internal shunt diode protects the device from damage. This protection mode avoids the compliance voltage penalty which results from a series diode that must be added if reversal protection is required in high-current loops.

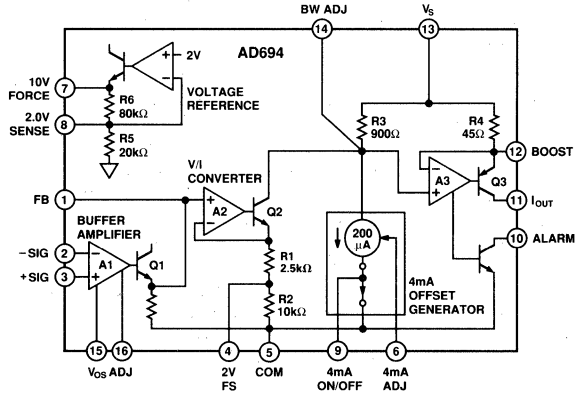
Wide Power Supply Range: +4.5 V to +36 V
Wide Output Compliance
Input Buffer Amplifier
Open-Loop Alarm
Optional External Pass Transistor to Reduce Self-Heating Errors
0.002% typ Nonlinearity

FUNCTIONAL BLOCK DIAGRAM



PRODUCT DESCRIPTION

The AD694 is a monolithic current transmitter that accepts high level signal inputs to drive a standard 4–20 mA current loop for the control of valves, actuators, and other devices commonly used in process control. The input signal is buffered by an input amplifier that can be used to scale the input signal or buffer the output from a current mode DAC. Precalibrated input spans of 0 V to 2 V and 0 V to 10 V are selected by simple pin strapping; other spans may be programmed with external resistor.

The output stage compliance extends to within 2 V of V_S and its special design allows the output voltage to extend below common in dual supply operation. An alarm warns of an open 4 to 20 mA loop or noncompliance of the output stage.

Active laser trimming of the AD694's thin film resistors results in high levels of accuracy without the need for additional adjustments and calibration. An external pass transistor may be used with the AD694 to off-load power dissipation, extending the temperature range of operation.

The AD694 is the ideal building block for systems requiring noise immune 4–20 mA signal transmission to operate valves, actuators, and other control devices, as well as for the transmission of process parameters such as pressure, temperature, or flow. It is recommended as a replacement for discrete designs in a variety of applications in industrial process control, factory automation, and system monitoring.

The AD694 is available in hermetically sealed, 16-pin cerdip and plastic SOIC, specified over the −40°C to +85°C industrial temperature range, and in a 16-pin plastic DIP, specified over the 0 to +70°C temperature range.

PRODUCT HIGHLIGHTS

1. The AD694 is a complete voltage in to 4–20 mA out current transmitter.
2. Pin programmable input ranges are pre-calibrated at 0 V to 2 V and 0 V to 10 V.
3. The input amplifier may be configured to buffer and scale the input voltage, or to serve as an output amplifier for current output DACs.
4. The output voltage compliance extends to within 2 V of the positive supply and below common. When operated with a 5 V supply, the output voltage compliance extends 30 V below common.
5. The AD694 interfaces directly to 8-, 10-, and 12-bit single supply CMOS and bipolar DACs.
6. The 4 mA zero current may be switched on and off with a TTL control pin, allowing 0–20 mA operation.
7. An open collector alarm warns of loop failure due to open wires or noncompliance of the output stage.
8. A monitored output is provided to drive an external pass transistor. The feature off-loads power dissipation to extend the temperature range of operation and minimize self-heating error.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

NOTES

[1]The single supply op amps of the AD694, lacking pull down current, may not reach 0.000 V at their outputs. For this reason, span, offset, and nonlinearity are specified with the input amplifiers operating in their linear range. The input voltage used for the tests is 5 mV to 2 V and 5 mV to 10 V for the two pre-calibrated input ranges. Span and zero accuracy are tested with the buffer amplifier configured as a follower.

[2]Offset at 4 mA out and 0 mA out are extrapolated to 0.000 V input from measurements made at 5 mV and at full scale. See Note 1.

[3]Nonlinearity is specified as the maximum deviation of the output, as a % of span, from a straight line drawn through the endpoints of the transfer function.

[4]Voltage reference drift guaranteed by the Box Method. The voltage reference output over temperature will fall inside of a box whose length is determined by the temperature range and whose height is determined by the maximum temperature coefficient multiplied by the temperature span in degrees C.

[5]Devices tested at these temperatures with a pass transistor. Allowable temperature range of operation is dependent upon internal power dissipation. Absolute maximum junction and case temperature should not be exceeded. See section: "Power Dissipation Considerations."

[6]Buffer amplifier specs for reference. Buffer amplifier offset and drift already included in Span and Zero accuracy specs above.

Specifications subject to change without notice.

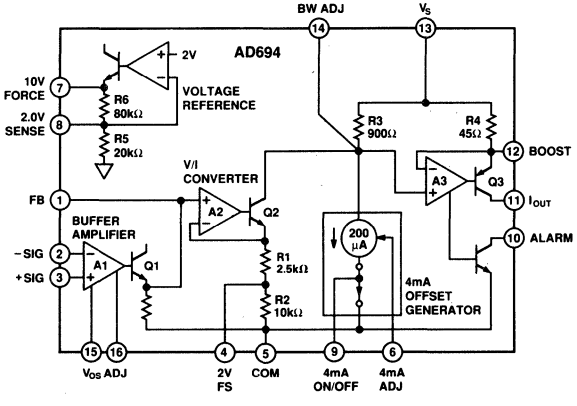

Figure 1. Functional Block Diagram

FUNCTIONAL DESCRIPTION

The operation of the AD694 can best be understood by dividing the circuit into three functional parts (see Figure 1). First, a single supply input amplifier buffers the high level, single-ended input signal. The buffer amplifier drives the second section, a voltage to current (V/I) converter, that makes a 0 to 16 mA signal dependent current.

The third section, a voltage reference and offset generator, is responsible for providing the 4 mA offset current signal.

BUFFER AMPLIFIER

The buffer amplifier is a single supply amplifier that may be used as a unity gain buffer, an output amplifier for a current output D/A converter, or as a gain block to amplify low level signals. The amplifier's PNP input stage has a common-mode range that extends from a few hundred mV below ground to within 2.5 V of V_S. The Class A output of the amplifier appears at Pin 1 (FB). The output range extends from about 1 mV above common to within 2.5 V of V_S when the amplifier is operated as a follower. The amplifier can source a maximum load of 5 kΩ, but can sink only as much as its internal 10 kΩ pull-down resistor allows.

19

V/I CONVERTER

The ground referenced, input signal from the buffer amplifier is converted to a 0 to 0.8 mA current by A2 and level shifted to the positive supply. A current mirror then multiplies this signal by a factor of 20 to make the signal current of 0 to 16 mA. This technique allows the output stage to drive a load to within 2 V of the positive supply (V_S). Amplifier A2 forces the voltage at Pin 1 across resistors R1 and R2 by driving the Darlington transistor, Q2. The high gain Darlington transmits the resistor current to its collector and to R3 (900 Ω). A3 forces the level shifted signal across the 45 Ω resistor to get a current gain of 20. The transfer function of the V/I stage is therefore:

$$I_{OUT} = (20 \times V_{(PIN1)}) / (R1 + R2)$$

resulting in a 0–16 mA output swing for a 0–10 V input. Tying Pin 4 (2 V FS) to ground shorts out R2 and results in a 2 V full-scale input for a 16 mA output span.

The output stage of the V/I converter is of a unique design that allows the I_{OUT} pin to drive a load below the common (substrate) potential of the device. The output transistor can always drive a load to a point 36 V below the positive supply (V_S). An optional NPN pass transistor can be added to transfer most of the power dissipation off-chip, to extend the temperature range of operation.

The output stage is current-limited at approximately 38 mA to protect the output from an overdrive at its inputs. The V/I will allow linear operation to approximately 24 mA. The V/I converter also has an open collector alarm (Pin 10) which warns of open-circuit condition at the I_{OUT} pin or of attempts to drive the output to a voltage greater than V_S −2 V.

4 mA OFFSET GENERATOR

This circuit converts a constant voltage from the voltage reference to a constant current of approximately 200 μA. This current is summed with the signal current at Pin 14 (BW Adjust), to result in a constant 4 mA offset current at I_{OUT}. The 4 mA Adj (Pin 6) allows the offset current to be adjusted to any current in the range of 2 mA to 4.8 mA. Pin 9 (4 mA On/Off) can shut off the offset current completely if it is lifted to 3.0 V or more, allowing 0 to 20 mA operation of the AD694. In normal 4–20 mA operation, Pin 9 is connected to ground.

VOLTAGE REFERENCE

A 2 V or 10 V voltage reference is available for user applications, selectable by pin-strapping. The 10 V option is available for supply voltages greater than 12.5 V, the 2 V output is available over the whole 4.5 V – 36 V power supply range. The reference can source up to 5 mA for user applications. A boost transistor can be added to increase the current drive capability of the 2 V mode.

APPLYING THE AD694

The AD694 can easily be connected for either dual or single supply operation, to operate from supplies as low as 4.5 V and as high as 36 V. The following sections describe the different connection configurations, as well as adjustment methods. Table I shows possible connection options.

Table I. Precalibrated Ranges for the AD694

Input Range	Output Range	Voltage Reference	Min V_S	Pin 9	Pin 4	Pin 8
0–2 V	4–20 mA	2 V	4.5 V	Pin 5	Pin 5	Pin 7
0–10 V	4–20 mA	2 V	12.5 V	Pin 5	Open	Pin 7
0–2.5 V	0–20 mA	2 V	5.0 V	≥3 V	Pin 5	Pin 7
0–12.5 V	0–20 mA	2 V	15.0 V	≥3 V	Open	Pin 7
0–2 V	4–20 mA	10 V	12.5 V	Pin 5	Pin 5	Open
0–10 V	4–20 mA	10 V	12.5 V	Pin 5	Open	Open
0–2.5 V	0–20 mA	10 V	12.5 V	≥3 V	Pin 5	Open
0–12.5 V	0–20 mA	10 V	15.0 V	≥3 V	Open	Open

BASIC CONNECTIONS: 12.5 V SINGLE SUPPLY OPERATION WITH 10 V FS

Figure 2 shows the minimal connections required for basic operation with a +12.5 V power supply, 10 V input span, 4–20 mA output span, and a 10 V voltage reference. The buffer amplifier is connected as a voltage follower to drive the V/I converter by connecting FB (Pin 1) to −Sig (Pin 2). 4 mA On/Off (Pin 9) is tied to ground (Pin 5) to enable the 4 mA offset current. The AD694 can drive a maximum load $R_L = [V_S - 2\ V] / 20\ mA$, thus the maximum load with a 12.5 V supply is 525 Ω.

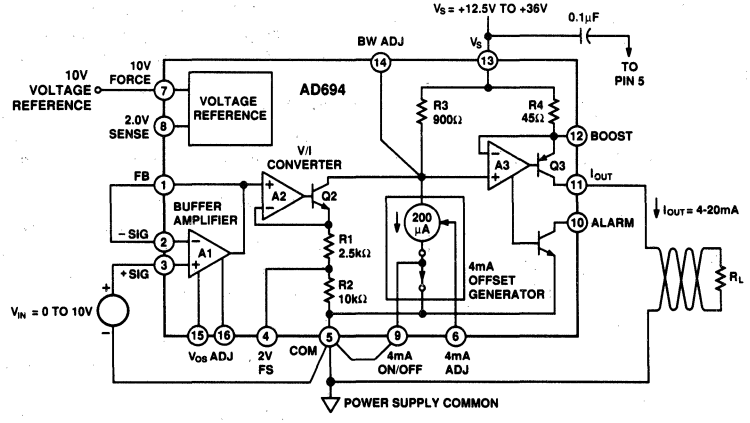

Figure 2. Minimal Connections for 0–10 V Single-Ended Input, 4–20 mA Output, 10 V Reference Output

SELECTING A 2 V FULL-SCALE INPUT

The 2 V full-scale option is selected by shorting Pin 4 (2 V FS) to Pin 5 (Common). The connection should be as short as possible; any parasitic resistance will affect the precalibrated span accuracy.

SELECTING THE 2 V VOLTAGE REFERENCE

The voltage reference is set to a 2 V output by shorting Pin 7 to Pin 8 (10 V Force to 2 V Sense). If desired, the 2 V reference can be set up for remote force and sense connection. Keep in mind that the 2 V Sense line carries a constant current of 100 μA that could cause an offset error over long wire runs. The 2 V reference option can be used with all supply voltages greater than 4.5 V.

An NPN boost transistor can be added in the 2 V mode to increase the current drive capability of the 2 V reference. The 10 V force pin is connected to the base of the NPN, and the NPN emitter is connected to the 2 V sense pin. The minimum V_S of the part increases by approximately 0.7 V.

4.5 V SINGLE SUPPLY OPERATION

For operation with a +4.5 V power supply, the input span and the voltage reference output must be reduced to give the amplifiers their required 2.5 V of head room for operation. This is done by adjusting the AD694 for 2 V full-scale input, and a voltage reference output of 2 V as described above.

GENERAL DESIGN GUIDELINES

A 0.1 μF decoupling capacitor is recommended in all applications from V_S (Pin 13) to Com (Pin 5). Additional components may be required if the output load is nonresistive, see section on driving nonresistive loads. The buffer amplifier PNP inputs should not be brought more than −0.3 V of common, or they will begin to source large amounts of current. Input protection resistors must be added to the inputs if there is a danger of this occurring. The output of the buffer amplifier, Pin 1 (FB), is not short circuit protected. Shorting this pin to ground or V_S with a signal present on the amplifier may damage it. Input signals should not drive Pin 1 (FB) directly; always use the buffer amplifier to buffer input signals.

DRIVING NONRESISTIVE LOADS

The AD694 is designed to be stable when driving resistive loads. Adding a 0.01 μF capacitor from I_{OUT} (Pin 11) to Com (Pin 5), as shown in Figure 3, insures the stability of the AD694 when driving inductive or poorly defined loads. This capacitor is recommended when there is any uncertainty as to the characteristics of the load.

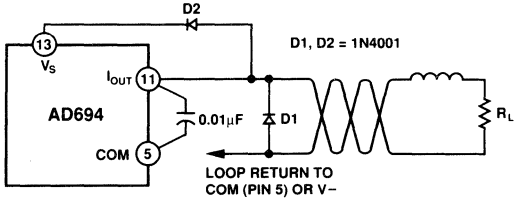

Figure 3. Capacitor Utilized When Driving Nonresistive Loads; Protection Diodes Used When Driving Inductive Loads

Additional protection is recommended when driving inductive loads. Figure 3 shows two protective diodes, D1 and D2, added to protect against voltage spikes that may extend above V_S or below common that could damage the AD694. These diodes should be used in addition to the 0.01 μF capacitor. When the optional NPN transistor is used, the capacitor and diodes should connect to the NPN emitter instead of Pin 11.

0–20 mA OPERATION

A 0–20 mA output range is available with the AD694 by removing the 4 mA offset current with the 4 mA On/Off pin. In normal 4–20 mA operation 4 mA On/Off (Pin 9) is tied to ground, enabling the 4 mA offset current. Tying Pin 9 to a potential of 3 V or greater turns off the 4 mA offset current; connecting Pin 9 to the 10 V reference, the positive supply, or a TTL control pin, is a convenient way to do this. In 0–20 mA mode the input span is increased by 20%, thus the precalibrated input spans of 2 V and 10 V become 2.5 V and 12.5 V. Minimum supply voltages for the two spans increase to 5 V and 15 V.

The 4 mA On/Off pin may also be used as a "jiggle pin" to unstick valves or actuators, or as a way to shut off a 4–20 mA loop entirely. Note that the pin only removes the 4 mA offset and not the signal current.

DUAL SUPPLY OPERATION

Figure 4 shows the AD694 operated in dual supply mode. (Note that the pass transistor is shown for illustration and is not required for dual supply operation.) The device is powered completely by the positive supply which may be as low as 4.5 V. The unique design of the output stage allows the I_{OUT} pin to extend below common to a negative supply. The output stage can source a current to a point 36 V below the positive supply. For example, when operated with a +12.5 V supply, the AD694 can source a current to a point as low as 23.5 V below common. This feature can simplify the interface to dual supply D/A converters by eliminating grounding and level-shifting problems while increasing the load that the transmitter is able to drive. Note that the I_{OUT} pin is the only pin that should be allowed to extend lower than −0.3 V of common.

OPERATION WITH A PASS TRANSISTOR

The AD694 can operate as a stand-alone 4–20 mA converter with no additional active components. However, provisions have been made to connect I_{OUT} to the base of an external NPN pass transistor as shown in Figure 4. This permits a majority of the power dissipation to be moved off-chip to enhance performance and extend the temperature range of operation. Note that the positive output voltage compliance is reduced by approximately 0.7 V, the V_{BE} of the pass device. A 50 Ω resistor should be added in series with the pass transistor collector, when the AD694 is operated with dual supplies, as shown in Figure 4. This will not reduce the voltage compliance of the output stage.

The external pass transistor selected should have a BV_{CEO} greater than the intended supply voltage with a sufficient power rating for continuous operation with 25 mA current at the supply voltage. Ft should be in the 10 MHz to 100 MHz range and β should be greater than 10 at a 20 mA emitter current. Heat sinking the external pass transistor is suggested.

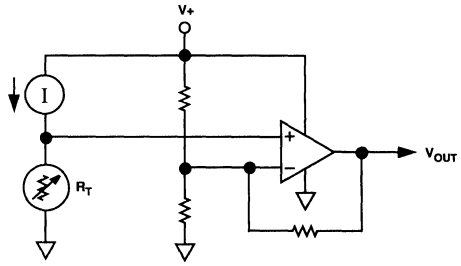
SIMPLIFIED BLOCK DIAGRAM



GENERAL DESCRIPTION

The AD22100 is a monolithic temperature sensor with on-chip signal conditioning. It can be operated over the temperature range –50°C to +150°C, making it ideal for use in numerous HVAC, instrumentation and automotive applications.

The signal conditioning eliminates the need for any trimming, buffering or linearization circuitry, greatly simplifying the system design and reducing the overall system cost.

The output voltage is proportional to the temperature times the supply voltage (ratiometric). The output swings from 0.25 V at –50°C to +4.75 V at +150°C using a single +5.0 V supply.

Due to its ratiometric nature, the AD22100 offers a cost effective solution when interfacing to an analog-to-digital converter. This is accomplished by using the ADC's +5 V power supply as a reference to both the ADC and the AD22100 (See Figure 1), eliminating the need for and cost of a precision reference.

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the AD22100 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

Typical Performance Curves

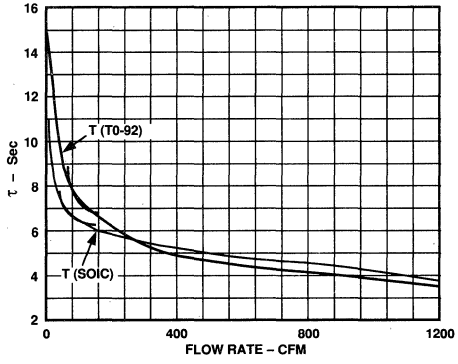

Figure 2. Thermal Response vs. Flow Rate

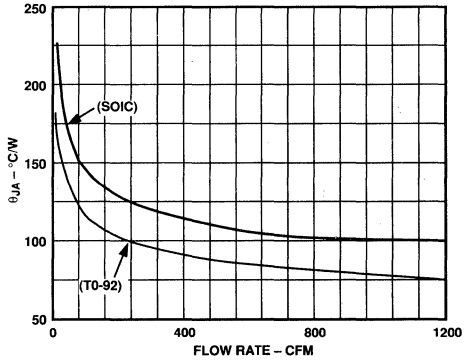

Figure 3. Thermal Resistance vs. Flow Rate

19

THEORY OF OPERATION

The AD22100 is a ratiometric temperature sensor IC whose output voltage is proportional to power supply voltage. The heart of the sensor is a proprietary temperature-dependent resistor, similar to an RTD, which is built into the IC. Figure 4 shows a simplified block diagram of the AD22100.

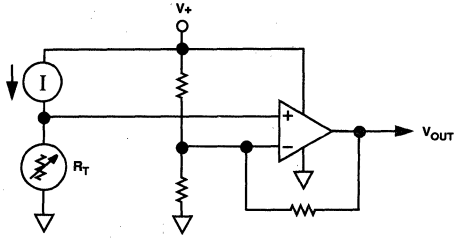

Figure 4. Simplified Block Diagram

The temperature-dependent resistor, labeled R_T, exhibits a change in resistance that is nearly linearly proportional to temperature. This resistor is excited with a current source that is proportional to power supply voltage. The resulting voltage across R_T is therefore both supply voltage proportional and linearly varying with temperature. The remainder of the AD22100 consists of an op amp signal conditioning block that takes the voltage across R_T and applies the proper gain and offset to achieve the following output voltage function:

$$V_{OUT} = (V+/5\ V) \times [1.375\ V + (22.5\ mV/°C) \times T_A]$$

ABSOLUTE ACCURACY AND NONLINEARITY SPECIFICATIONS

Figure 5 graphically depicts the guaranteed limits of accuracy for the AD22100 and shows the performance of a typical part. As the output is very linear, the major sources of error are offset, i.e., error at room temperature, and span error, i.e., deviation from the theoretical 22.5 mV/°C. Demanding applications can achieve improved performance by calibrating these offset and gain errors so that only the residual nonlinearity remains as a significant source of error.

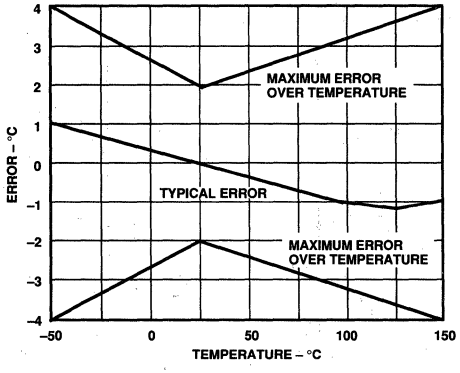

Figure 5. Typical AD22100 Performance

OUTPUT STAGE CONSIDERATIONS

As previously stated, the AD22100 is a voltage output device. A basic understanding of the nature of its output stage is useful for proper application. Note that at the nominal supply voltage of 5.0 V, the output voltage extends from 0.25 V at –50°C to +4.75 V at +150°C. Furthermore, the AD22100 output pin is capable of withstanding an indefinite short circuit to either ground or the power supply. These characteristics are provided by the output stage structure shown in Figure 6.

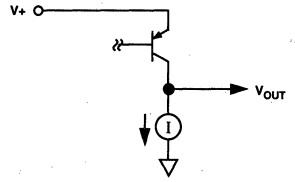

Figure 6. Output Stage Structure

The active portion of the output stage is a PNP transistor with its emitter connected to the V+ supply and collector connected to the output node. This PNP transistor sources the required amount of output current. A limited pull-down capability is provided by a fixed current sink of about –80 μA. (Here, "fixed" means the current sink is fairly insensitive to either supply voltage or output loading conditions. The current sink capability is a function of temperature, increasing its pull-down capability at lower temperatures.)

Due to its limited current sinking ability, the AD22100 is incapable of driving loads to the V+ power supply and is instead intended to drive grounded loads. A typical value for short circuit current limit is 7 mA, so devices can reliably source 1 mA or 2 mA. However, for best output voltage accuracy and minimal internal self-heating, output current should be kept below 1 mA. Loads connected to the V+ power supply should be avoided as the current sinking capability of the AD22100 is fairly limited. These considerations are typically not a problem when driving a microcontroller analog to digital converter input pin (see MICROPROCESSOR A/D INTERFACE ISSUES).

RATIOMETRICITY CONSIDERATIONS

The AD22100 will operate with slightly better accuracy than that listed in the data sheet specifications if the power supply is held constant. This is because the AD22100's output voltage varies with both temperature and supply voltage, with some errors. The ideal transfer function describing the output voltage is:

$$(V+/5\ V) \times [1.375\ V + (22.5\ mV/°C) \times T_A]$$

The ratiometricity error is defined as the percent change away from the ideal transfer function as the power supply voltage changes within the operating range of +4 V to +6 V. For the AD22100 this error is typically less than 1%. A movement from the ideal transfer function by 1% at +25°C, with a supply voltage varying from 5.0 V to 5.50 V, results in a 1.94 mV change in output voltage or 0.08°C error. This error term is greater at higher temperatures because the output (and error term) is directly proportional to temperature. At 150°C, the error in output voltage is 4.75 mV or 0.19°C.

For example, with V_S = 5.0 V, and T_A = +25°C, the nominal output of the AD22100 will be 1.9375 V. At V_S = 5.50 V, the nominal output will be 2.1313 V, an increase of 193.75 mV. A proportionality error of 1% is applied to the 193.75 mV, yielding an error term of 1.9375 mV. This error term translates to a variation in output voltage of 2.1293 V to 2.3332 V. A 1.94 mV error at the output is equivalent to about 0.08°C error in accuracy.

If we substitute 150°C for 25°C in the above example, then the error term translates to a variation in output voltage of 5.2203 V to 5.2298 V. A 4.75 mV error at the output is equivalent to about 0.19°C error in accuracy.

MOUNTING CONSIDERATIONS

If the AD22100 is thermally attached and properly protected, it can be used in any measuring situation where the maximum range of temperatures encountered is between –50°C and +150°C. Because plastic IC packaging technology is employed, excessive mechanical stress must be avoided when fastening the device with a clamp or screw-on heat tab. Thermally conductive epoxy or glue is recommended for typical mounting conditions. In wet or corrosive environments, an electrically isolated metal or ceramic well should be used to shield the AD22100. Because the part has a voltage output (as opposed to current), it offers modest immunity to leakage errors, such as those caused by condensation at low temperatures.

THERMAL ENVIRONMENT EFFECTS

The thermal environment in which the AD22100 is used determines two performance traits: the effect of self-heating on accuracy and the response time of the sensor to rapid changes in temperature. In the first case, a rise in the IC junction temperature above the ambient temperature is a function of two variables; the power consumption of the AD22100 and the thermal resistance between the chip and the ambient environment θ_{JA}. Self-heating error in °C can be derived by multiplying the power dissipation by θ_{JA}. Because errors of this type can vary widely for surroundings with different heat sinking capacities, it is necessary to specify θ_{JA} under several conditions. Table I shows how the magnitude of self-heating error varies relative to the environment. A typical part will dissipate about 2.2 mW at room temperature with a 5 V supply and negligible output loading. In still air, without a "heat sink," the table below indicates a θ_{JA} of 190°C/W, yielding a temperature rise of 0.4°C. Thermal rise will be considerably less in either moving air or with direct physical connection to a solid (or liquid) body.

Table I. Thermal Resistance (TO-92)

Medium	θ_{JA} (°C/Watt)	τ (sec) *
Aluminum Block	60	2
Moving Air**		
Without Heat Sink	75	3.5
Still Air		
Without Heat Sink	190	15

*The time constant τ is defined as the time to reach 63.2% of the final temperature change.
**1200 CFM.

Response of the AD22100 output to abrupt changes in ambient temperature can be modeled by a single time constant τ exponential function. Figure 7 shows typical response time plots for a few media of interest.

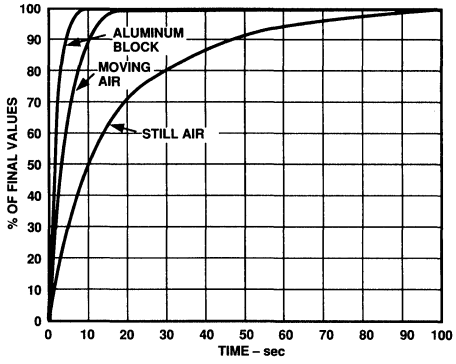

Figure 7. Response Time

The time constant τ is dependent on θ_{JA} and the thermal capacities of the chip and the package. Table I lists the effective τ (time to reach 63.2% of the final value) for a few different media. Copper printed circuit board connections were neglected in the analysis; however, they will sink or conduct heat directly through the AD22100's solder plated copper leads. When faster response is required, a thermally conductive grease or glue between the AD22100 and the surface temperature being measured should be used.

MICROPROCESSOR A/D INTERFACE ISSUES

The AD22100 is especially well suited to providing a low cost temperature measurement capability for microprocessor/microcontroller based systems. Many inexpensive 8-bit microprocessors now offer an onboard 8-bit ADC capability at a modest cost premium. Total "cost of ownership" then becomes a function of the voltage reference and analog signal conditioning necessary to mate the analog sensor with the microprocessor ADC. The AD22100 can provide an ideal low cost system by eliminating the need for a precision voltage reference and any additional active components. The ratiometric nature of the AD22100 allows the microprocessor to use the same power supply as its ADC reference. Variations of hundreds of millivolts in the supply voltage have little effect as both the AD22100 and the ADC use the supply as their reference. The nominal AD22100 signal range of 0.25 V to 4.75 V (–50°C to +150°C) makes good use of the input range of a 0 V to 5 V ADC. A single resistor and capacitor are recommended to provide immunity to the high speed charge dump glitches seen at many microprocessor ADC inputs (see Figure 1).

An 8-bit ADC with a reference of 5 V will have a least significant bit (LSB) size of 5 V/256 = 19.5 mV. This corresponds to a nominal resolution of about 0.87°C.

USE WITH A PRECISION REFERENCE AS THE SUPPLY VOLTAGE

While the ratiometric nature of the AD22100 allows for system operation without a precision voltage reference, it can still be used in such systems. Overall system requirements involving other sensors or signal inputs may dictate the need for a fixed precision ADC reference. The AD22100 can be converted to absolute voltage operation by using a precision reference as the supply voltage. For example, a 5.00 V reference can be used to power the AD22100 directly. Supply current will typically be 500 μA which is usually within the output capability of the reference. A large number of AD22100s may require an additional op amp buffer, as would scaling down a 10.00 V reference that might be found in "instrumentation" ADCs typically operating from ±15 V supplies.

Monolithic Accelerometer with Signal Conditioning

ADXL05*

FEATURES

Complete Acceleration Measurement System on a Single Monolithic IC
Full-Scale Measurement Range: ±5 g
Self-Test on Digital Command
Single Supply Operation: +5 V
Sensitivity Precalibrated to 200 mV/g
Internal Buffer Amplifier for User Adjustable Span and Zero-g Levels
Frequency Response: DC to 4 kHz
Post Filtering with External Passive Components
High Shock Survival: >1000 g Unpowered
Other Accelerometer Products, Measuring Different g Levels, Are Available

GENERAL DESCRIPTION

The ADXL05 is a low noise member of the ADXL50 family of products. It is a complete acceleration measurement system on a single monolithic IC. Three external capacitors and a +5 volt regulated power supply are all that is required to measure accelerations up to ±5 g. Device sensitivity is factory trimmed to a scale factor of 200 mV/g resulting in a full-scale output swing of ±1 volt for a ±5 g applied acceleration. Its zero-g output level is +1.8 volts.

A TTL compatible self-test function can electrostatically deflect the sensor beam at any time to verify device functionality.

For convenience, the ADXL05 has an internal buffer amplifier with a full 0.25 V to 4.75 V output range. This may be used to set the zero-g level and change the output sensitivity by using external resistors. External capacitors may be added to the resistor network to provide 1 or 2 poles of filtering. No external active components are required to interface directly to most analog-to-digital converters (ADCs) or microcontrollers.

The ADXL05 uses a capacitive measurement method. The analog output voltage is directly proportional to acceleration and is fully scaled, referenced and temperature compensated, resulting in high accuracy and linearity over a wide temperature range. Internal circuitry implements a forced-balance control loop that improves accuracy by compensating for mechanical sensor variations.

The ADXL05 is powered from a standard +5 V supply and is robust, allowing its use in harsh industrial and automotive environments. It will survive shocks of 1000 g unpowered. The ADXL05 is available in a hermetic 10-pin TO-100 metal can. Contact factory for grades of performance and temperature ranges.

FUNCTIONAL BLOCK DIAGRAM AND PINOUT

ANALOG DEVICES

Monolithic Accelerometer With Signal Conditioning

ADXL50*

FEATURES

Complete Acceleration Measurement System on a Single Monolithic IC
Full-Scale Measurement Range: ±50 g
Self-Test on Digital Command
+5 V Single Supply Operation
Sensitivity Precalibrated to 19 mV/g
Internal Buffer Amplifier for User Adjustable Sensitivity and Zero-g Level
Frequency Response: DC to 10 kHz
Post Filtering with External Passive Components
High Shock Survival: >2000 g Unpowered
Other Versions Available: ADXL05 (±5 g) ADXL181 (+880 g, −150 g)

GENERAL DESCRIPTION

The ADXL50 is a complete acceleration measurement system on a single monolithic IC. Three external capacitors and a +5 volt power supply are all that is required to measure accelerations up to ±50 g. Device sensitivity is factory trimmed to 19 mV/g, resulting in a full-scale output swing of ±0.95 volts for a ±50 g applied acceleration. Its zero g output level is +1.8 volts.

A TTL compatible self-test function can electrostatically deflect the sensor beam at any time to verify device functionality.

For convenience, the ADXL50 has an internal buffer amplifier with a full 0.25 V to 4.75 V output range. This may be used to set the zero-g level and change the output sensitivity by using external resistors. External capacitors may be added to the resistor network to provide 1 or 2 poles of filtering. No external active components are required to interface directly to most analog-to-digital converters (ADCs) or microcontrollers.

The ADXL50 uses a capacitive measurement method. The analog output voltage is directly proportional to acceleration, and is fully scaled, referenced and temperature compensated, resulting in high accuracy and linearity over a wide temperature range. Internal circuitry implements a forced-balance control loop that improves accuracy by compensating for any mechanical sensor variations.

The ADXL50 is powered from a standard +5 V supply and is robust for use in harsh industrial and automotive environments and will survive shocks of more than 2000 g unpowered.

The ADXL50 is available in a hermetic 10-pin TO-100 metal can, specified over the 0°C to +70°C commercial, and −40°C to +85°C industrial temperature ranges. Contact factory for availability of devices specified for operation over the −40°C to +105°C automotive and −55°C to +125°C military temperature ranges and for availability of 883B devices.

NOTES
[1]As measured at the preamplifier output, V_{PR} with 15 g p-p @ 100 Hz applied.
[2]Specification refers to the maximum change in parameter from its initial value at +25°C to its worst case value at T_{MIN} or T_{MAX}.
[3]As measured at V_{PR}.
[4]BW = 10 Hz to 1 kHz. A capacitor, C2, greater than or equal to 0.022 µF, must be connected from the oscillator decoupling capacitor pin to ground.
[5]The axis of sensitivity of the device is a straight line drawn through the package along its most sensitive axis. For the 10-pin header (TO-100) package, this line passes through Pin 5 and the tab. See device connection and orientation figures.
[6]Best Fit Straight Line. Full scale = 50 g.
[7]Alignment error is specified as the angle between the true and indicated axis of sensitivity. The ADXL50 output will be the true acceleration times the cosine of the alignment error angle.
[8]Transverse sensitivity is measured with an applied acceleration which is 90° (i.e., transverse) from the indicated axis of sensitivity. Transverse sensitivity error is specified as the percent of transverse acceleration which appears at the V_{PR} output. This is the algebraic sum of the alignment and the inherent sensor sensitivity errors.
Specifications subject to change without notice.
*Contact factory for availability.

NOTES
[1]For outline information see Package Information section.
[2]Contact factory for availability.

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the ADXL50 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

ADXL50 PIN DESCRIPTION

+5 V	The power supply input pin.
C2	Connection for an external bypass capacitor (nominally 0.022 μF) used to prevent oscillator switching noise from interfering with other ADXL50 circuitry. Please see the section on component selection.
C1	Connections for the demodulator capacitor, nominally 0.022 μF. See the section on component selection for application information.
COM	The power supply common (or "ground") connection.
V_{REF}	Output of the internal 3.4 V voltage reference.
ST	The digital self-test input. It is both CMOS and TTL compatible.
V_{PR}	The ADXL50 preamplifier output providing an output voltage of 19 mV per g of acceleration.
V_{OUT}	Output of the uncommitted buffer amplifier.
V_{IN-}	The inverting input of the uncommitted buffer amplifier.

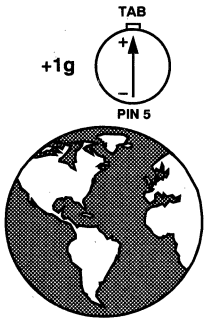

Figure 1. Output Polarity at V_{PR}

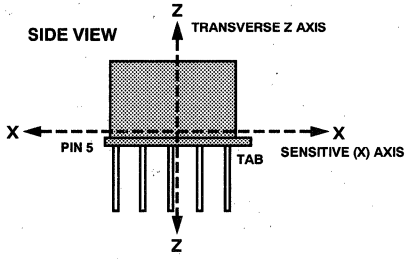

Figure 2a. Sensitive X and Transverse Z Axis

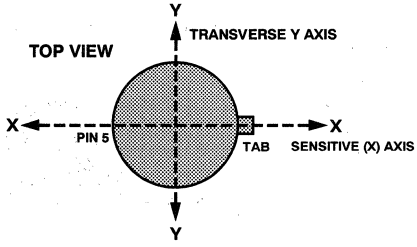

Figure 2b. Sensitive X and Transverse Y Axis

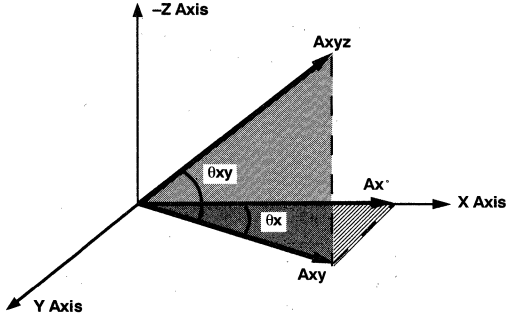

Figure 2c. A Vector Analysis of an Acceleration Acting Upon the ADXL50 in Three Dimensions

Polarity of the Acceleration Output

The polarity of the ADXL50 output is shown in the Figure 1. When oriented to the earth's gravity (and held in place), the ADXL50 will experience an acceleration of +1 g. This corresponds to a change of approximately +19 mV at the V_{PR} output pin. Note that the polarity will be reversed to a negative going signal at the buffer amplifier output V_{OUT}, due to its inverting configuration.

Mounting Considerations

There are three main causes of measurement error when using accelerometers. The first two are alignment and transverse sensitivity errors. The third source of error is due to resonances or vibrations of the sensor in its mounting fixture.

Errors Due to Misalignment

The ADXL50 is a sensor designed to measure accelerations that result from an applied force. Because these forces act on the sensor in a vector manner, the alignment of the sensor to the force to be measured may be critical.

The ADXL50 responds to the component of acceleration on its sensitive X axis. Figures 2a and 2b show the relationship between the sensitive "X" axis and the transverse "Z" and "Y" axes as they relate to the TO-100 package.

Figure 2c describes a three dimensional acceleration vector (A_{XYZ}) which might act on the sensor, where A_X is the component of interest. To determine A_X, first, the component of acceleration in the XY plane (A_{XY}) is found using the cosine law:

$$A_{XY} = A_{XYZ}\,(cos\theta_{XY})\ then$$
$$A_X = A_{XY}\,(cos\theta_X)$$

Therefore: *Typical* $V_{PR} = 19\ mV/g\ (A_{XYZ})\ (cos\theta_{XY})\ cos\theta_X$.

Note that an ideal sensor will react to forces along or at angles to its sensitive axis but will reject signals from its various transverse axes, i.e., those exactly 90° from the sensitive "X" axis. But even an ideal sensor will produce output signals if the transverse signals are not exactly 90° to the sensitive axis. An acceleration that is acting on the sensor from a direction different from the sensitive axis will show up at the ADXL50 output at a reduced amplitude.

Table I. Ideal Output Signals for Off Axis Applied Accelerations Disregarding Device Alignment and Transverse Sensitivity Errors

θ_X	% of Signal Appearing at Output	Output in g's for a 50 g Applied Acceleration
0	100%	50 (On Axis)
1°	99.98%	49.99
2°	99.94%	49.97
3°	99.86%	49.93
5°	99.62%	49.81
10°	98.48%	49.24
30°	86.60%	43.30
45°	70.71%	35.36
60°	50.00%	25.00
80°	17.36%	8.68
85°	8.72%	4.36
87°	5.25%	2.63
88°	3.49%	1.75
89°	1.7%	0.85
90°	0%	0.00 (Transverse Axis)

Table I shows the percentage signals resulting from various θ_X angles. Note that small errors in alignment have a negligible effect on the output signal. A 1° error will only cause a 0.02% error in the signal. Note, however, that a signal coming 1° off of the transverse axis (i.e., 89° off the sensitive axis) will still contribute 1.7% of its signal to the output. Thus large transverse signals could cause output signals as large as the signals of interest.

Table I may also be used to approximate the effect of the ADXL50's internal errors due to misalignment of the die to the package. For example: a 1 degree sensor alignment error will allow 1.7% of a transverse signal to appear at the output. In a nonideal sensor, transverse sensitivity may also occur due to inherent sensor properties. That is, if the sensor physically moves due to a force applied exactly 90° to its sensitive axis, then this might be detected as an output signal, whereas an ideal sensor would reject such signals. In every day use, alignment errors may cause a small output peak with accelerations applied close to the sensitive axis but the largest errors are normally due to large accelerations applied close to the transverse axis.

Errors Due to Mounting Fixture Resonances
A common source of error in acceleration sensing is resonance of the mounting fixture. For example, the circuit board that the ADXL50 mounts to may have resonant frequencies in the same range as the signals of interest. This could cause the signals measured to be larger than they really are. A common solution to this problem is to dampen these resonances by mounting the ADXL50 near a mounting post or by adding extra screws to hold the board more securely in place.

When testing the accelerometer in your end application, it is recommended that you test the application at a variety of frequencies in order to ensure that no major resonance problems exist.

GLOSSARY OF TERMS

Acceleration: Change in velocity per unit time.

Acceleration Vector: Vector describing the net acceleration acting upon the ADXL50 (A_{XYZ}).

g: A unit of acceleration equal to the average force of gravity occurring at the earth's surface. A g is approximately equal to 32.17 feet/s^2, or 9.807 meters/s^2.

Nonlinearity: The maximum deviation of the ADXL50 output voltage from a best fit straight line fitted to a plot of acceleration vs. output voltage, calculated as a % of the full-scale output voltage (@ 50 g).

Resonant Frequency: The natural frequency of vibration of the ADXL50 sensor's central plate (or "beam"). At its resonant frequency of 24 kHz, the ADXL50's moving center plate has a peak in its frequency response with a Q of 3 or 4.

Sensitivity: The output voltage change per g unit of acceleration applied, specified at the V_{PR} pin in mV/g.

Sensitive Axis (X) The most sensitive axis of the accelerometer sensor. Defined by a line drawn between the package tab and Pin 5 in the plane of the pin circle. See Figures 2a and 2b.

Sensor Alignment Error: Misalignment between the ADXL50's on-chip sensor and the package axis, defined by Pin 5 and the package tab.

Total Alignment Error: Net misalignment of the ADXL50's on-chip sensor and the measurement axis of the application. This error includes errors due to sensor die alignment to the package, and any misalignment due to installation of the sensor package in a circuit board or module.

Transverse Acceleration: Any acceleration applied 90° to the axis of sensitivity.

Transverse Sensitivity Error: The percent of a transverse acceleration that appears at the V_{PR} output. For example, if the transverse sensitivity is 1%, then a +10 g transverse acceleration will cause a 0.1 g signal to appear at V_{PR} (1% of 10 g). Transverse sensitivity can result from a sensitivity of the sensor to transverse forces or from misalignment of the internal sensor to its package.

Transverse Y Axis: The axis perpendicular (90°) to the package axis of sensitivity in the plane of the package pin circle. See Figure 2.

Transverse Z Axis: The axis perpendicular (90°) to both the package axis of sensitivity and the plane of the package pin circle. See Figure 2.

THEORY OF OPERATION

The ADXL50 is a complete acceleration measurement system on a single monolithic IC. It contains a polysilicon surface-micro machined sensor and signal conditioning circuitry. The ADXL50 is capable of measuring both positive and negative acceleration to a maximum level of ±50 g.

Figure 16 is a simplified view of the ADXL50's acceleration sensor at rest. The actual structure of the sensor consists of 42 unit cells and a common beam. The differential capacitor sensor consists of independent fixed plates and a movable "floating" central plate which deflects in response to changes in relative motion. The two capacitors are series connected, forming a capacitive divider with a common movable central plate. A force balance technique counters any impeding deflection due to acceleration and servos the sensor back to its 0 g position.

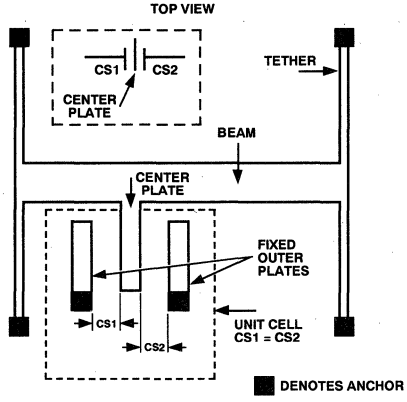

Figure 16. A Simplified Diagram of the ADXL50 Sensor at Rest

Figure 17 shows the sensor responding to an applied acceleration. When this occurs, the common central plate or "beam" moves closer to one of the fixed plates while moving further from the other. The sensor's fixed capacitor plates are driven deferentially by a 1 MHz square wave: the two square wave amplitudes are equal but are 180° out of phase from one another. When at rest, the values of the two capacitors are the same and therefore, the voltage output at their electrical center (i.e., at the center plate) is zero.

When the sensor begins to move, a mismatch in the value of their capacitance is created producing an output signal at the central plate. The output amplitude will increase with the amount of acceleration experienced by the sensor. Information concerning the direction of beam motion is contained in the phase of the signal with synchronous demodulation being used to extract this information. Note that the sensor needs to be positioned so that the measured acceleration is along its sensitive axis.

Figure 18 shows a block diagram of the ADXL50. The voltage output from the central plate of the sensor is buffered and then applied to a synchronous demodulator. The demodulator is also supplied with a (nominal) 1 MHz clock signal from the same oscillator which drives the fixed plates of the sensor. The demodulator will rectify any voltage which is in sync with its clock signal. If the applied voltage is in sync and in phase with the clock, a positive output will result. If the applied voltage is in sync but 180° out of phase with the clock, then the demodulator's output will be negative. All other signals will be rejected. An external capacitor, C1, sets the bandwidth of the demodulator.

The output of the synchronous demodulator drives the preamp —an instrumentation amplifier buffer which is referenced to +1.8 volts. The output of the preamp is fed back to the sensor through a 3 MΩ isolation resistor. The correction voltage required to hold the sensor's center plate in the 0 g position is a direct measure of the applied acceleration and appears at the V_{PR} pin.

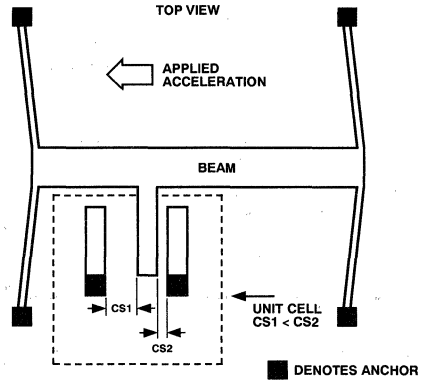

Figure 17. The ADXL50 Sensor Momentarily Responding to an Externally Applied Acceleration

When the ADXL50 is subjected to an acceleration, its capacitive sensor begins to move creating a momentary output signal. This is signal conditioned and amplified by the demodulator and preamp circuits. The dc voltage appearing at the preamp output is then fed back to the sensor and electrostatically forces the center plate back to its original center position.

At 0 g the ADXL50 is calibrated to provide +1.8 volts at the V_{PR} pin. With an applied acceleration, the V_{PR} voltage changes to the voltage required to hold the sensor stationary for the duration of the acceleration and provides an output which varies directly with applied acceleration.

The loop bandwidth corresponds to the time required to apply feedback to the sensor and is set by external capacitor C1. The loop response is fast enough to follow changes in g level up to and exceeding 1 kHz. The ADXL50's ability to maintain a flat response over this bandwidth keeps the sensor virtually motionless. This essentially eliminates any nonlinearity or aging effects due to the sensor beam's mechanical spring constant, as compared to an open-loop sensor.

An uncommitted buffer amplifier provides the capability to adjust the scale factor and 0 g offset level over a wide range. An internal reference supplies the necessary regulated voltages for powering the chip and +3.4 volts for external use.

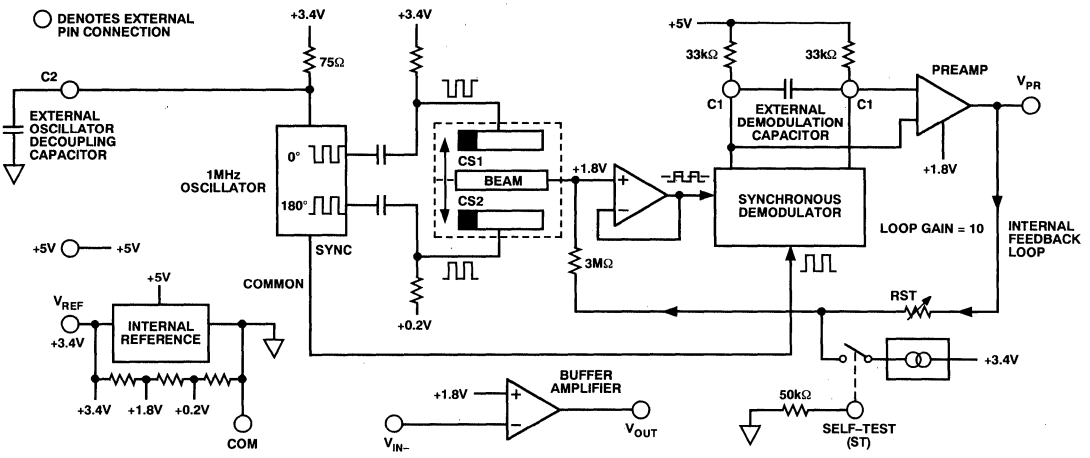

Figure 18. ADXL50 Functional Block Diagram

The sensor's tight mechanical spacing allows it to be electrostatically deflected to full scale while operating on a 5 volt supply. A self-test is initiated by applying a TTL "high" level voltage (>+2.0 V) to the ADXL50's self-test pin which causes the chip to apply a deflection voltage to the beam which moves it an amount equal to −50 g (the negative full-scale output of the device). Note that the ±10% tolerance of the self-test circuit is not proportional to the sensitivity error, see Self-Test section.

The output of the ADXL50's preamplifier is 1.8 V at 0 g acceleration with an output range of ±0.95 V for a ±50 g input, i.e., 19 mV/g. An uncommitted buffer amplifier has been included on-chip to enhance the user's ability to offset the 0 g signal level and to amplify and filter the signal. Access is provided to both the inverting input and the output of this amplifier via pins V_{OUT} and V_{IN-}, while the noninverting input is connected internally to a +1.8 V reference. The +1.8 V is derived from a resistor divider connected to the 3.4 V reference.

BASIC CONNECTIONS FOR THE ADXL50

Figure 19 shows the basic connections needed for the ADXL50 to measure accelerations in the ±50 g range with an output scale factor 40 mV/g corresponding to a 2.5 V 0 g level, a ±2.0 V full-scale swing around 0 g and a 3 dB bandwidth of approximately 1 kHz.

In general, the designer will need to take into account the initial zero g bias when designing circuits. For the ADXL50J this offset is 1.8 V ± 250 mV. When microprocessors and software

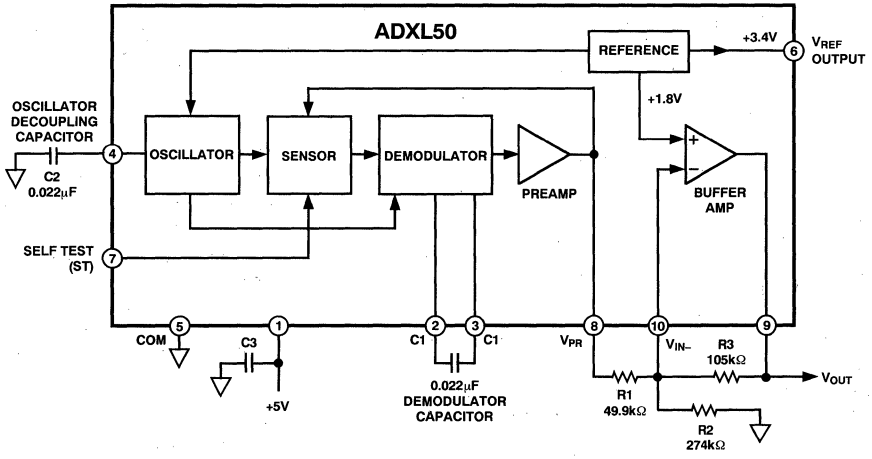

Figure 19. ADXL50 Application Providing an Output Sensitivity of 40 mV/g, a +2.5 V 0 g Level and a Bandwidth of 1 kHz

calibration are used and there is a desire to eliminate trim potentiometers, the design should leave room at either supply rail to account for signal swing and or variations in initial zero g bias.

For example, in the circuit in Figure 19, the initial zero g bias of ±250 mV will be reflected to the output by the gain of the R3/R1 network, resulting in an output offset of ±526 mV worst case. The offset, combined with a full-scale signal of 50 g, (+2.0 V) will cause the output buffer amplifier to saturate at the supply rail.

The full ±2.25 V output swing of the buffer amplifier can be utilized if the user is able to trim the zero-g bias to exactly 2.5 V. In applications where the full-scale range will be ±25 g or less, a bias trim such as that shown in Figure 20 will almost always be required.

VARYING THE OUTPUT SENSITIVITY AND 0 g LEVEL USING THE INTERNAL BUFFER AMPLIFIER

The uncommitted buffer amplifier may be used to change the output sensitivity to provide useful full-scale ranges of ±50 g and below. Table II provides recommended resistor values for several standard ranges down to ±10 g. As the full-scale range is decreased, buffer amplifier gain is increased, and the noise contribution as a percentage of full scale will also increase. For all ranges, the signal-to-noise ratio can be improved by reducing the circuit bandwidth, either by increasing the demodulator capacitor, C1, or by adding a post filter using the buffer amplifier.

Table II. Recommended Resistor Values for Setting the Circuit of Figure 20 to Several Common Full-Scale Ranges

FS (g)	Buffer Gain	SF in mV/g	R1	R3	R2
±50.0	2.11	40	49.9 k	105 k	100 k
±40.0	2.63	50	39.2 k	103 k	100 k
±30.8	3.42	65	40.2 k	137 k	100 k
±26.7	3.95	75	28.7 k	113 k	100 k
±20.0	5.26	100	26.1 k	137 k	100 k
±10.0	10.53	200	23.7 k	249 k	100 k

Note that the value of resistor R1 should be selected to limit the output current flowing into V_{PR} to less than 25 μA (to provide a safety margin). For a "J" grade device, this current is equal to:

$$I_{PR} = \frac{(2.05\ V - \textit{The peak full-scale output voltage at } V_{PR}) - 1.8\ V}{R1 \textit{ in ohms}}$$

For a ±50 g full-scale range, R1 needs to be 49.9 kΩ or larger in value; but at the lower full-scale g ranges, if the V_{PR} swing is much less, then it is possible to use much lower resistance values. For this table, the circuit of Figure 20 is used, as a 0 g offset trim will be required for most applications. In all cases, it is assumed that the zero-g bias level is 2.5 V with an output span of ±2 V.

Note that for full scales below ±20 g the self-test is unlikely to operate correctly because the V_{PR} pull-down current is not guaranteed to be large enough to drive R1 to the required −1.0 V swing. In these cases, the self-test command will cause V_{OUT} to saturate at the rail, and it will be necessary to monitor the self-test at V_{PR}. Self-test can remain operational at V_{PR} for all g ranges listed by keeping R1 > 49.9 kΩ, with the subsequent tradeoff that the required values for R3 will become very large. The user always has the option of adding external gain and filtering stages after the ADXL50 to make lower full-scale ranges.

Measuring Full-Scale Accelerations Less than ±5 g

Applications, such as motion detection, and tilt sensing, have signal amplitudes in the 1 g to 2 g range. Although designed for higher full-scale ranges, the ADXL50 may be adapted for use in low g applications; the two main design considerations are noise and 0 g offset drift (BH, KH grades recommended).

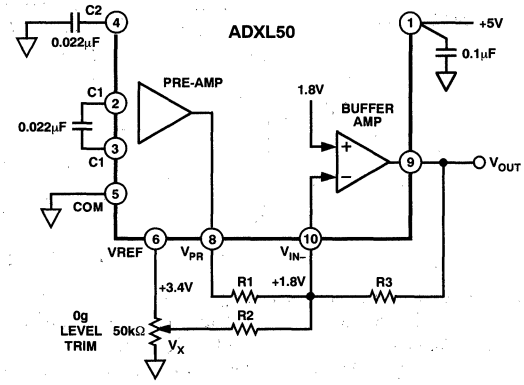

Figure 20. ADXL50 Circuit Using the Buffer Amplifier to Set the Output Scaling and 0 g Offset Level

At its full 1 kHz bandwidth, the ADXL50 will typically exhibit 1 g p-p of noise. With ±50 g accelerations this is generally not a problem, but at a ±2 g full-scale level the signal-to-noise ratio will be very poor. However, reducing the bandwidth to 100 Hz or less considerably improves the S/N ratio. Figure 25 shows the relationship between ADXL50 bandwidth and noise.

The ADXL50 exhibits offset drifts that are typically 0.02 g per °C but which may be as large as 0.1 g per °C. With the buffer amplifier configured for a 2 g full scale, the ADXL50 will typically drift 1/2 of its full-scale range with a 50°C increase in temperature.

There are several cures for offset drift. If a dc response is not required, for example in motion sensing or vibration measurement applications, consider ac coupling the acceleration signal to remove the effects of offset drift. See the section on ac coupling.

Periodically recalibrating the accelerometer's 0 g level is another option. Autozero or long term averaging can be used to remove long term drift using a microprocessor or the autozero circuit of Figure 29. Be sure to keep the buffer amplifier's full-scale output range much larger than the measurement range to allow for the 0 g level drift.

CALCULATING COMPONENT VALUES FOR SCALE FACTOR AND 0 g SIGNAL LEVEL

The ADXL50 buffer's scale factor is set by −R3/R1 (since the amplifier is in the inverter mode).

As an example, if the desired span is ±2.0 V for a ±50 g input, then R3/R1 should be chosen such that

$$R3/R1 = V_{OUT}\ Span/V_{PR}\ Span = 2.00/0.95 = 2.105 \quad (1)$$

where V_{PR} span is the output from the preamplifier and V_{OUT} span is the buffer amplifier's output, giving

$$R3 = 2.105 \times R1 \quad (2)$$

In noncritical applications, a resistor, R2, may simply be connected between V_{IN-} and common to provide an approximate 0 g offset level (see Figure 19). In this simplified configuration R2 is found using:

$$R2 = (1.8\ V \times R3)/(V_{OUT} @ 0\ g - 1.8\ V)$$

When used with a trim potentiometer, as in Figure 20, resistor R2 sets the 0 g offset range and also sets the resolution of the offset trim. A value of 100 kΩ is typical. Increasing R2 above this value makes trimming the offset easier, but may not provide enough trim range to set V_{OUT} equal to +2.5 V for all devices.

To provide an output span of ±2.00 V, with a 0 g output of +2.5 V, R1 could be set to the standard value of 49.9 kΩ and from Equation 2, R3 = 105 kΩ.

For Figure 20, the circuit transfer function is:

$$V_{OUT} = \left(\frac{R3}{R1}(1.8\ V - V_{PR})\right) + \left(\frac{R3}{R2}(1.8\ V - V_X)\right) + 1.8\ V$$

The summing amplifier configuration allows noninteractive trimming of offset and span. Since V_{PR} is not always exactly 1.8 V at 0 g, it will contribute to output offset. Therefore, span must be trimmed first, followed by 0 g offset adjustment.

LOAD DRIVE CAPABILITIES OF THE V_{PR} AND BUFFER OUTPUTS

The V_{PR} and the buffer amplifier outputs are both capable of driving a load to voltage levels approaching that of the supply rail. However, both outputs are limited in how much current they can supply, affecting component selection.

V_{PR} Output

The V_{PR} pin has the ability to source current up to 500 μA but only has a sinking capability of 30 μA which limits its ability to drive loads. It is recommended that the buffer amplifier be used in most applications, to avoid loading down V_{PR}. In standard ±50 g applications, the resistor R1 from V_{PR} to V_{IN-} is recommended to have a value greater than 50 kΩ to reduce loading effects.

Capacitive loading of the V_{PR} pin should be minimized. A load capacitance between the V_{PR} pin and common will introduce an offset of approximately 1 mV for every 10 pF of load. The V_{PR} pin may be used to directly drive an A/D input or other source as long as these sensitivities are taken into account. It is always preferable to drive A/D converters or other sources using the buffer amplifier (or an external op amp) instead of the V_{PR} pin.

Buffer Amplifier Output

The buffer output can drive a load to within 0.25 V of either power supply rail and is capable of driving 1000 pF capacitive loads. Note that a capacitance connected across the buffer feedback resistor for low-pass filtering does not appear as a capacitive load to the buffer. The buffer amplifier is limited to sourcing or sinking a maximum of 100 μA. Component values for the resistor network should be selected to ensure that the buffer amplifier can drive the filter under worst case transient conditions.

SELF-TEST FUNCTION

The digital self-test input is compatible with both CMOS and TTL signals. A Logic "1" applied to the self-test (ST) input will cause an electrostatic force to be applied to the sensor which will cause it to deflect to the approximate negative full-scale output of the device. Accordingly, a correctly functioning accelerometer will respond by initiating an approximate −1 volt output change at V_{PR}. If the ADXL50 is experiencing an acceleration when the self-test is initiated, the V_{PR} output will equal the algebraic sum of the two inputs. The output will stay at the self-test level as long as the ST input remains high and will return to the 0 g level when the ST voltage is removed.

A self-test output that varies more than ±10% from the nominal −1.0 V change indicates a defective beam or a circuit problem such as an open or shorted pin or component.

Operating the ADXL50's buffer amplifier at Gains > 2, to provide full-scale outputs of less than ±50 g, may cause the self-test output to overdrive the buffer into saturation. The self-test may still be used in the case, but the change in the output must then be monitored at the V_{PR} pin instead of the buffer output.

Note that the value of the self-test delta is not an exact indication of the sensitivity (mV/g) of the ADXL50 and, therefore, may not be used to calibrate the device for sensitivity error.

In critical applications, it may be desirable to monitor shifts in the zero-g bias voltage from its initial value. A shift in the 0 g bias level may indicate that the 0 g level has shifted which may warrant an alarm.

POWER SUPPLY DECOUPLING

The ADXL50 power supply should be decoupled with a 0.1 μF ceramic capacitor from +5 V pin of the ADXL50 to common using very short component leads. For other decoupling considerations, see EMI/RFI section.

OSCILLATOR DECOUPLING CAPACITOR, C2

An oscillator decoupling capacitor, C2, is used to remove 1 MHz switching transients in the sensor excitation signal, and is required for proper operation of the ADXL50. A ceramic capacitor with a minimum value of 0.022 μF is recommended from the oscillator decoupling capacitor pin to common. Small amounts of capacitor leakage due to a dc resistance greater than 1 MΩ will not affect operation (i.e., a high quality capacitor is not needed here). As with the power supply bypass capacitor, very short component leads are recommended. Although 0.022 μF is a good typical value, it may be increased for reasons of convenience, but doing this will not improve the noise performance of the ADXL50.

DEMODULATOR CAPACITOR, C1

The demodulator capacitor is connected across Pins 2 and 3 to filter the demodulated signal from the sensor beam and to set the bandwidth of the force balance control loop. This capacitor may be used to approximately set the bandwidth of the accelerometer. A capacitor is always required for proper operation.

The frequency response of the ADXL50 exhibits a single pole roll-off response whose nominal 3 dB frequency is set by the following equation:

$$f_{3\,dB} = (28.60/C1\ in\ \mu F)\ \pm 40\%$$

A nominal value of 0.022 μF is recommended for C1. In general, the design bandwidth should be set 40% higher than the minimum desired system bandwidth due to the ±40% tolerance.

A minimum value of 0.015 μF is required, (over temperature and system life), to prevent device instability or oscillation. The demodulation capacitor should be a low leakage, low drift ceramic type with an NPO (best) or X7R (good) dielectric.

In general, it's best to use the recommended 0.022 μF capacitor across the demodulator pins and perform any additional low-pass filtering using the buffer amplifier. Using a large denominator capacitor for low-pass filtering has the disadvantage that the capacitive sensor will be slow to respond to rapid changes in acceleration and, therefore, the full shock survivability of the device could be compromised. The use of the buffer for low-pass filtering generally results in smaller capacitance values and better overall performance. It is also a convenient and more precise way to set the system bandwidth. Post filtering allows bandwidth to be controlled accurately by component selection and avoids the ±40% demodulation tolerance. Note that signal noise is proportional to the square root of the bandwidth of the ADXL50 and may be a consideration in component selection—see section on noise.

Care should be taken to reduce or eliminate any leakage paths from the demodulator capacitor pins to common or to the +5 V pin. Even a small imbalance in the leakage paths from these pins will result in offset shifts in the zero-g bias level. As an example, an unbalanced parasitic resistance of 30 MΩ from either demodulator pin to ground will result in an offset shift at V_{PR} of approximately 50 mV. Conformal coating of PC boards with a high impedance material is recommended to avoid leakage problems due to aging or moisture.

REDUCING THE AVERAGE POWER CONSUMPTION OF THE ADXL50

The ADXL50 is a versatile accelerometer that can be used in a wide variety of applications. In some battery powered applications, such as shipping recorders, power consumption is a critical parameter. The ADXL50 typically draws 10 mA current from a 5 V power supply which may exceed the power budgeted for the accelerometer.

For such applications, the ADXL50 can be successfully power cycled, where the power is turned on only during the period when data is sampled. Figure 21 illustrates the power-on settling of the ADXL50 during cycling where the output amplifier has a gain of one with no filtering. The settling time-constant is approximately 0.12 ms, waiting 1 ms before sampling ensures maximally accurate readings.

For example, to reduce the average power to 5 mW from its typical 50 mW, the power should be on 10% of the time. With the power on for 1 ms and off for 9 ms, a maximum sample rate of 100 Hz is achievable. Further reduction in average power can be realized with lower sample rates.

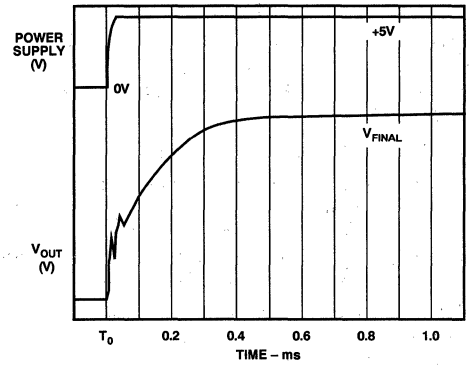

Figure 21. Power-On Settling Time when Power Cycling

SYSTEM BANDWIDTH CONTROL AND POST FILTERING

Unlike piezoresistive sensors, the resonant frequency of the ADXL50's capacitive sensor element is typically greater than 20 kHz and does not limit the useful bandwidth of the device. Usually, the resonant frequency of the beam appears as a peak in the bandwidth response at approximately 24 kHz with a Q of 3 to 4, as shown in Figure 22.

When using the recommended 0.022 μF demodulator capacitor, be advised that the nominal 1300 Hz pole it establishes within the device can vary ±40%. Therefore, if additional low-pass filtering is used—at frequencies much above 600 Hz—the two poles may interact and result in a net circuit bandwidth that is lower than expected.

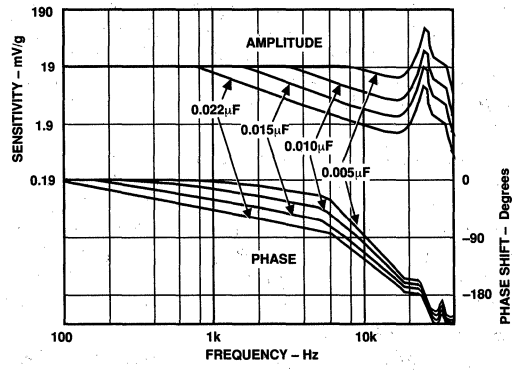

Figure 22. Frequency Response of the ADXL50 for Various Demodulator Capacitors

RECOMMENDED COMPONENT VALUES FOR VARIOUS FULL SCALE RANGES AND A 300Hz BANDWIDTH

FULL SCALE	mV per g	3dB BW (Hz)	R1a kΩ	R1b kΩ	R3 kΩ	R2 kΩ	C4 μF
±10 g	200	300	5	21.5	249	100	0.0022
±20 g	100	300	5	23.7	137	100	0.0039
±40 g	50	300	10	34	105	100	0.0056
±50 g	40	300	10	45.3	105	100	0.0056

$$3dB\ BW = \frac{1}{2\pi\ R3\ C4}$$

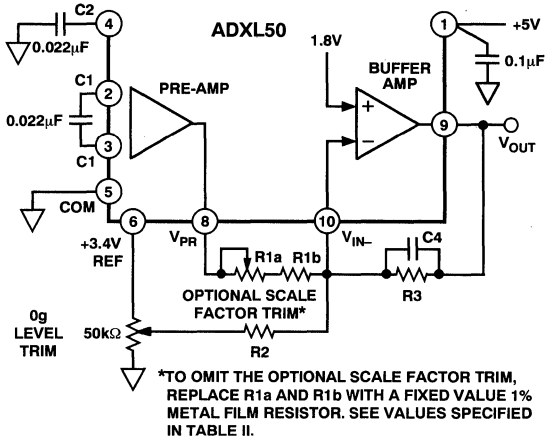

Figure 23. Using the Buffer Amplifier to Provide One Pole Post Filtering Plus Scale Factor and 0 g Level Trimming

ONE POLE POST FILTERING

Figure 23 shows the ADXL50 buffer amplifier connected to provide one pole post filtering, 0 g offset trimming, and output scaling. The table included with the figure lists practical component values for various full-scale g levels and approximate circuit bandwidths. For bandwidths other than those listed, use the formula:

$$Capacitor\ C4\ in\ Farads = 1/(2\ \pi \times R3\ in\ Ohms \times 3\ dB\ BW\ in\ Hertz)$$

or simply scale the value of capacitor C4 accordingly; i.e., for a ±20 g application with a 50 Hz bandwidth, the value of C4 will need to be twice as large as its 100 Hz value or 0.012 μF × 2 = 0.024 μF. The closest standard value of 0.022 μF should then be used.

TWO POLE POST FILTERING

Figure 24 shows a circuit which uses the ADXL50's buffer amplifier to provide two pole post filtering. An AD820 external op amp allows noninteractive adjustment of 0 g offset and scale factor. Component values for the two pole filter were selected to operate the buffer at unity gain with a Q of one.

2 POLE FILTER COMPONENT VALUES

3dB BW(Hz)	C3μF	C4μF
300	0.027	0.0033
100	0.082	0.01
30	0.27	0.033
10	0.82	0.1

OFFSET & SCALING AMPLIFIER COMPONENT VALUES

FULL SCALE	mV per g	GAIN	R4a kΩ	R4b kΩ	R5 kΩ
±10 g	200	10.53	5	21.5	249
±20 g	100	5.26	5	23.7	137
±40 g	50	2.63	10	34	105
±50 g	40	2.11	10	45.3	105

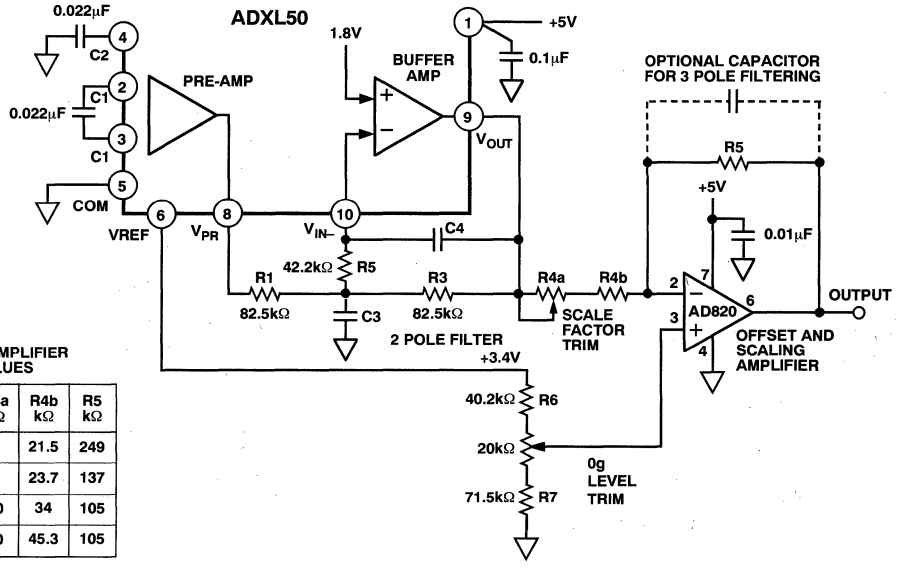

Figure 24. Circuit Providing Two Pole Post Filtering and 0 g Offset and Scale Factor Trimming

19

Capacitors C3 and C4 are chosen to provide the desired 3 dB bandwidth. Component values are specified for bandwidths of 10 Hz, 30 Hz, 100 Hz, and 300 Hz. For other 3 dB bandwidths simply scale the capacitor values; i.e., for a 3 dB bandwidth of 20 Hz, divide the 10 Hz bandwidth numbers by 2.0. The nominal buffer amplifier output will be +1.8 V ± 19 mV/g. Note that the ADXL50's self-test will be fully functional since the buffer amplifier is operated at unity gain and resistor R1 is large. The external op amp offsets and scales the output to provide a +2.5 V ± 2 V output over a wide range of full-scale g levels. The external op amp may be omitted in high g, low gain applications.

NOISE CONSIDERATIONS

The output noise of the ADXL50 scales with the square root of its bandwidth. The noise floor may be reduced by lowering the bandwidth of the ADXL50 either by increasing the value of the demodulator capacitor or by adding an external filter.

The typical rms noise of the ADXL50J with a bandwidth of 100 Hz and a noise density of 125 $\mu V/\sqrt{Hz}$ is estimated as follows:

$$Noise\ (rms) = (125\ \mu V/\sqrt{Hz})\ \sqrt{100} = 1.25\ mV\ rms$$

Peak-to-peak noise may be estimated with the following equation:

$$Noise\ p\text{-}p = (6.6)\ Noise\ rms$$

Peak-to-peak noise is thus estimated at 8.25 mV or approximately 0.4 g p-p. The ADXL50 noise is characteristic of white noise. Typical rms and p-p noise for various 3 dB bandwidths is estimated in Figure 25.

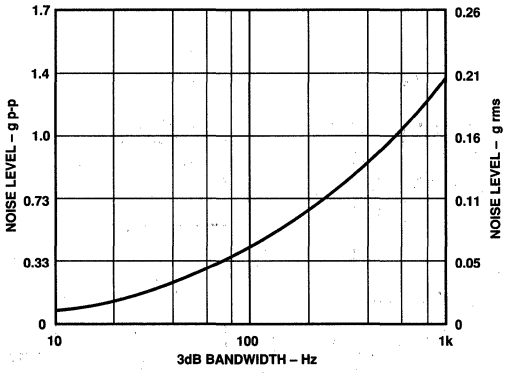

Figure 25. ADXL50 Noise Level and Resolution vs. −3 dB Bandwidth

Because the ADXL50's noise is for all practical purposes Gaussian in amplitude distribution, the highest noise amplitudes have the smallest (yet nonzero) probability. Peak-to-peak noise is, therefore, difficult to measure and can only be estimated due to its statistical nature. Table III is useful for estimating the probabilities of exceeding various peak values, given the rms value.

Table III.

Nominal Peak-to-Peak Value	% of Time that Noise will Exceed Nominal Peak-to-Peak Value
2.0 × rms	32%
3.0 × rms	13%
4.0 × rms	4.6%
5.0 × rms	1.2%
6.0 × rms	0.27%
6.6 × rms	**0.1%**
7.0 × rms	0.046%
8.0 × rms	0.006%

AC COUPLING V_{PR} TO BUFFER INPUT

If a dc response is not required, as in applications such as motion detection or vibration measurement, then ac coupling should be considered. In low g applications, the output voltage change due to acceleration is small compared to the 0 g offset voltage drift. Because ac coupling removes the dc component of the output, the preamp output signal may be amplified considerably without increasing the 0 g level drift. The most effective way to ac couple the ADXL50 is between the preamp output at V_{PR} and the buffer input, V_{IN-}, as shown in Figure 26.

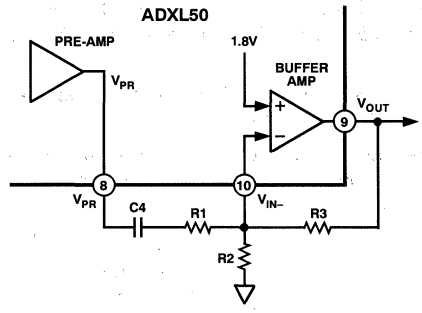

Figure 26. AC Coupling the V_{PR} Output to the Buffer Input

Using this configuration, the system's ac response is now rolled off—at the low frequency end at F_L, and at the high frequency end at F_H. The normalized frequency response of the system can be seen in Figure 27.

The low frequency roll-off, F_L, due to the ac coupling network is:

$$F_L = 1/(2\ \pi\ R1\ C4)$$

The high frequency roll-off F_H is determined by the dominant pole of the system which is controlled by either the demodulator capacitor and its associated time-constant or by a dominant post filter.

As a consequence of ac coupling, any constant acceleration component will not be detected (because this too is a dc voltage present at the V_{PR} output). The self-test feature, if used, must be monitored at V_{PR}, rather than at the buffer output.

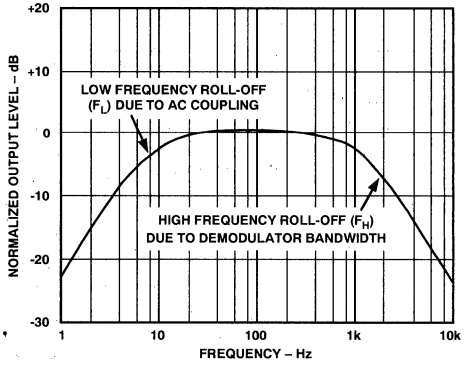

Figure 27. Normalized Output Level vs. Frequency for a Typical Application Using AC Coupling Between V_{PR} and Buffer Amplifier

MINIMIZING EMI/RFI

The architecture of the ADXL50 and its use of synchronous demodulation make the device immune to most electro-magnetic (EMI) and radio frequency (RFI) interference. The use of synchronous demodulation allows the circuit to reject all signals except those at the frequency of the oscillator driving the sensor element. However, the ADXL50 does have a sensitivity to RFI that is within ±5 kHz of the internal oscillator's nominal frequency of 1 MHz. The internal oscillator frequency will exhibit part to part variation in the range of 0.6 MHz to 1.4 MHz.

In general the effect is difficult to notice as the interference must match the internal oscillator within ±5 kHz and must be large in amplitude. For example: a 1 MHz interference signal of 20 mV p-p applied to the +5 V power supply pin will produce a 200 mV p-p signal at the V_{PR} pin if the internal oscillator and interference signals are matched exactly. If the same 20 mV interference is applied but 5 kHz above or below the internal oscillator's frequency, the signal level at V_{PR} will only be 20 mV p-p in amplitude.

Power supply decoupling, short component leads (especially for capacitors C1 and C2), physically small (surface mount, etc.) components and attention to good grounding practices all help to prevent RFI and EMI problems. Please consult the factory for applications assistance in instances where this may be of concern.

SELF-CALIBRATING THE ADXL50

If a calibrated shaker is not available, both the 0 g level and scale factor of the ADXL50 may be easily set to fair accuracy by using a self-calibration technique based on the 1 g (average) acceleration of the earth's gravity. Figure 28 shows how gravity and package orientation affect the ADXL50's output (TO-100 package shown). Note that the output polarity is that which appears at V_{PR}; the output at V_{OUT} will have the opposite sign. With its axis of sensitivity in the vertical plane, the ADXL50 should register a 1 g acceleration, either positive or negative, depending on orientation. With the axis of sensitivity in the horizontal plane, no acceleration (0 g) should be indicated.

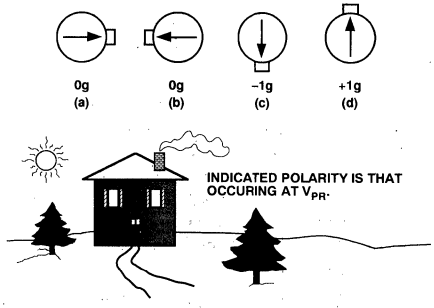

Figure 28. Using the Earth's Gravity to Self-Calibrate the ADXL50

To self-calibrate the ADXL50, place the accelerometer on its side with its axis of sensitivity oriented as shown in "a." The 0 g offset potentiometer, Rt, is then roughly adjusted for midscale: +2.5 V at the buffer output. If the optional scale factor trimming is to be used, it should be adjusted next.

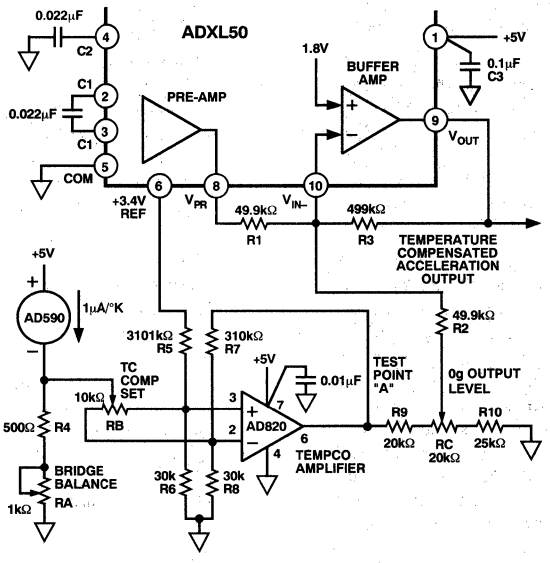
Next, the package axis should be oriented as in "c" (pointing down) and the output reading noted. The package axis should then be rotated 180° to position "d" and the scale factor potentiometer, R1a, adjusted so that the output voltage indicates a change of 2 g's in acceleration. For example, if the circuit scale factor at the buffer output is 100 mV per g, then the scale factor trim should be adjusted so that an output change of 200 mV is indicated.

Adjusting the circuit's scale factor will have some effect on its 0 g level so this should be readjusted, as before, but this time checked in both positions "a" and "b." If there is a difference in the 0 g reading, a compromise setting should be selected so that the reading in each direction is equidistant from +2.5 V. Scale factor and 0 g offset adjustments should be repeated until both are correct. Temporarily placing a capacitor across the buffer amplifier's feedback resistor will reduce output noise and so aid in trimming the device. Note that, for high full-scale g ranges, ±2 g may be a very small fraction of the full-scale range and device nonlinearity will, therefore, affect the circuit's high g level accuracy.

Compensating for the 0 g Drift of the ADXL50 Accelerometer
The circuit of Figure 29 provides a linear temperature compensation for the ADXL50. Figure 30 shows the 0 g drift over temperature for a typical ADXL50 with and without this circuit. As shown by Figure 30, the linear portion of the drift curve has been subtracted out. In effect, the curve has been rotated counterclockwise until it is horizontal, leaving just the bow of the curve: that portion which is not linear. As shown by Figure 30, over a +25°C to +70°C range, a 10× reduction in drift is achieved.

The circuit of Figure 29 is essentially a temperature sensor coupled to a Whetstone bridge. The AD590 provides a 1 μA/°K current output whose voltage scale factor is set by resistor RA. The bridge circuit subtracts out the nominal 298 mV output of the AD590 at +25°C and leaves only the change in temperature, which is what is needed. Without the bridge, the 298 mV room temperature "offset" would "swamp" the much smaller change in output with temperature.

Resistors R5 and R6 form a resistor divider (one half of the bridge) which divides down the +3.4 V reference output of the ADXL50 to 0.3 V which appears at the noninverting input of the AD820 op amp. Resistors R7 and R8 form the other half of the bridge, and because they have the same ratio as R5 and R6, the op amp will have a +3.4 V output at room temperature.



CALIBRATION PROCEEDURE:
AT T_{MIN} OR LOWER TEMP CAL POINT...

1. SET RB ALL THE WAY TO ONE SIDE.
2. ADJUST RA FOR +3.4V AT TEST POINT "A."
3. SET RC FOR +2.5V V_{OUT} (AT PIN 9 OF ADXL50).
4. TEMPORARILY CONNECT A 1.5kΩ RESISTOR BETWEEN THE CENTER OF RB AND GROUND.
5. ADJUST RB FOR +2.5V AT V_{OUT}.
6. REMOVE THE 1.5kΩ RESISTOR. V_{OUT} SHOULD NOT CHANGE.
7. GO TO T_{MAX} OR HIGH TEMP CAL POINT.
8. READJUST RB FOR +2.5V.
9. CALIBRATION COMPLETE.

Monolithic Accelerometer with Signal Conditioning

ADXL181*

FEATURES

Complete Acceleration Measurement System on a Single Monolithic IC
Full-Scale Measurement Range:
+5 V Supply: –125 g, +250 g
+12 V Supply: –150 g, +880 g
Self-Test on Digital Command
Single Supply Operation
Sensitivity Precalibrated to 8 mV/g
Internal Buffer Amplifier for User Adjustable Sensitivity and Zero-g Level
Frequency Response: DC to 3 kHz
Post Filtering with External Passive Components
High Shock Survival: >2000 g Unpowered
Other Products Available Providing Different Sensitivities and Full-Scale Ranges

GENERAL DESCRIPTION

The ADXL181 is a complete acceleration measurement system on a single monolithic IC, using a surface micromachined capacitive measurement method. The analog output voltage is directly proportional to acceleration and is fully scaled, referenced, and temperature compensated, resulting in high accuracy and linearity over a wide temperature range. Internal circuitry implements a force-balance control loop that compensates for any mechanical sensor variations.

A TTL compatible self-test feature can electrostatically deflect the sensor beam at any time to verify device functionality.

An internal buffer amplifier has a 0.25 V to V_S – 0.25 V output range. This may be used to gain and offset adjust the output signal so that it has a symmetrical output range. The amplifier can also be used to gain adjust and filter the sensor output. No external active components are necessary to connect the output signal directly to an analog-to-digital converter or microcontroller.

The ADXL181 is packaged in a hermetic 10-pin TO-100 metal can. Contact factory for availability of devices with specific temperature ranges and performance.

ANALOG DEVICES

Low Power, Programmable Temperature Controller

TMP01*

FEATURES

−55°C to +125°C (−67°F to +257°F) Operation
±0.5°C Accuracy Over Temperature (typ)
Temperature-Proportional Voltage Output
User Programmable Temperature Trip Points
User Programmable Hysteresis
20 mA Open Collector Trip Point Outputs
TTL/CMOS Compatible
Single-Supply Operation (4.5 V to 13.2 V)
Low Cost 8-Pin DIP and SO Packages

APPLICATIONS

Over/Under Temperature Sensor and Alarm
Board Level Temperature Sensing
Temperature Controllers
Electronic Thermostats
Thermal Protection
HVAC Systems
Industrial Process Control
Remote Sensors

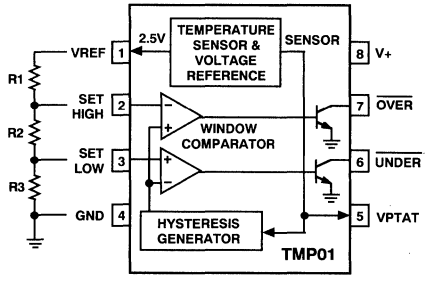
GENERAL DESCRIPTION

The TMP01 is a temperature sensor which generates a voltage output proportional to absolute temperature and a control signal from one of two outputs when the device is either above or below a specific temperature range. Both the high/low temperature trip points and hysteresis (overshoot) band are determined by user-selected external resistors. For high volume production, these resistors are available on-board.

The TMP01 consists of a bandgap voltage reference combined with a pair of matched comparators. The reference provides both a constant 2.5 V output and a voltage proportional to absolute temperature (VPTAT) which has a precise temperature coefficient of 5 mV/K and is 1.49 V (nominal) at +25°C. The comparators compare VPTAT with the externally set temperature trip points and generate an open-collector output signal when one of their respective thresholds has been exceeded.

*Protected by U.S. Patent No. 5,195,827.

FUNCTIONAL BLOCK DIAGRAM



Hysteresis is also programmed by the external resistor chain and is determined by the total current drawn out of the 2.5 V reference. This current is mirrored and used to generate a hysteresis offset voltage of the appropriate polarity after a comparator has been tripped. The comparators are connected in parallel, which guarantees that there is no hysteresis overlap and eliminates erratic transitions between adjacent trip zones.

The TMP01 utilizes proprietary thin film resistors in conjunction with production laser trimming to maintain a temperature accuracy of ±2°C (typ) over the rated temperature range, with excellent linearity. The open-collector outputs are capable of sinking 20 mA, enabling the TMP01 to drive control relays directly. Operating from a +5 V supply, quiescent current is only 500 μA (max).

The TMP01 is available in the low cost 8-pin epoxy mini-DIP and SO (small outline) packages, and in die form.

NOTES
[1]θ_{JA} is specified for device in socket (worst case conditions).
[2]θ_{JA} is specified for device mounted on PCB.

CAUTION

1. Stresses above those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. This is a stress rating only and functional operation at or above this specification is not implied. Exposure to the above maximum rating conditions for extended periods may affect device reliability.
2. Digital inputs and outputs are protected, however, permanent damage may occur on unprotected units from high energy electrostatic fields. Keep units in conductive foam or packaging at all times until ready to use. Use proper antistatic handling procedures.
3. Remove power before inserting or removing units from their sockets.

GENERAL DESCRIPTION

The TMP01 is a very linear voltage-output temperature sensor, with a window comparator that can be programmed by the user to activate one of two open-collector outputs when a predetermined temperature setpoint voltage has been exceeded. A low drift voltage reference is available for setpoint programming.

The temperature sensor is basically a very accurately temperature-compensated, bandgap-type voltage reference with a buffered output voltage proportional to absolute temperature (VPTAT), accurately trimmed to a scale factor of 5 mV/K. See the applications information following.

The low drift 2.5 V reference output VREF is easily divided externally with fixed resistors or potentiometers to accurately establish the programmed heat/cool setpoints, independent of temperature. Alternatively, the setpoint voltages can be supplied by other ground-referenced voltage sources such as user-programmed DACs or controllers. The high and low setpoint voltages are compared to the temperature sensor voltage, thus creating a two-temperature thermostat function. In addition, the total output current of the reference (I_{VREF}) determines the magnitude of the temperature hysteresis band. The open-collector outputs of the comparators can be used to control a wide variety of devices.

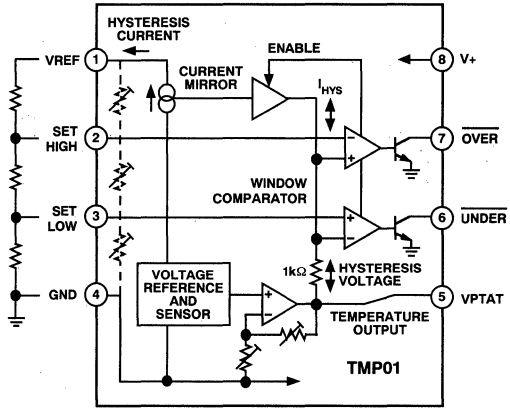

Figure 1. Detailed Block Diagram

19

Temperature Hysteresis

The temperature hysteresis is the number of degrees beyond the original setpoint temperature that must be sensed by the TMP01 before the setpoint comparator will be reset and the output disabled. Figure 2 shows the hysteresis profile. The hysteresis is programmed by the user by setting a specific load on the reference voltage output VREF. This output current I_{VREF} is also called the hysteresis current, which is mirrored internally and fed to a buffer with an analog switch.

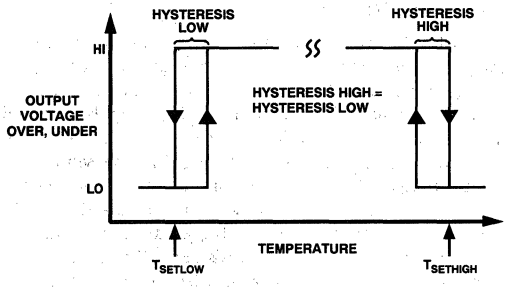

Figure 2. TMP01 Hysteresis Profile

After a temperature setpoint has been exceeded and a comparator tripped, the buffer output is enabled. The output is a current of the appropriate polarity which generates a hysteresis offset voltage across an internal 1000 Ω resistor at the comparator input. The comparator output remains "on" until the voltage at the comparator input, now equal to the temperature sensor voltage VPTAT summed with the hysteresis offset, has returned to the programmed setpoint voltage. The comparator then returns LOW, deactivating the open-collector output and disabling the hysteresis current buffer output. The scale factor for the programmed hysteresis current is:

$$I_{HYS} = I_{VREF} = 5\ \mu A/°C + 7\mu A$$

Thus since VREF = 2.5 V, with a reference load resistance of 357 kΩ or greater (output current 7 μA or less), the temperature setpoint hysteresis will be zero degrees. See the temperature programming discussion below. Larger values of load resistance will only decrease the output current below 7 μA and will have no effect on the operation of the device. The amount of hysteresis is determined by selecting a value of load resistance for VREF, as shown below.

Programming the TMP01

In the basic fixed-setpoint application utilizing a simple resistor ladder voltage divider, the desired temperature setpoints are programmed in the following sequence:

1. Select the desired hysteresis temperature.
2. Calculate the hysteresis current I_{VREF}.
3 Select the desired setpoint temperatures.
4. Calculate the individual resistor divider ladder values needed to develop the desired comparator setpoint voltages at SETHIGH and SETLOW.

The hysteresis current is readily calculated, as shown above. For example, for 2 degrees of hysteresis, I_{VREF} = 17 μA. Next, the setpoint voltages $V_{SETHIGH}$ and V_{SETLOW} are determined using the VPTAT scale factor of 5 mV/K = 5 mV/(°C + 273.15), which is 1.49 V for +25°C. We then calculate the divider resistors, based on those setpoints. The equations used to calculate the resistors are:

$$V_{SETHIGH} = (T_{SETHIGH} + 273.15)(5\ mV/°C)$$

$$V_{SETLOW} = (T_{SETLOW} + 273.15)(5\ mV/°C)$$

$$R1\ (k\Omega) = (V_{VREF} - V_{SETHIGH})/I_{VREF} = (2.5\ V - V_{SETHIGH})/I_{VREF}$$

$$R2\ (k\Omega) = (V_{SETHIGH} - V_{SETLOW})/I_{VREF}$$

$$R3\ (k\Omega) = V_{SETLOW}/I_{VREF}$$

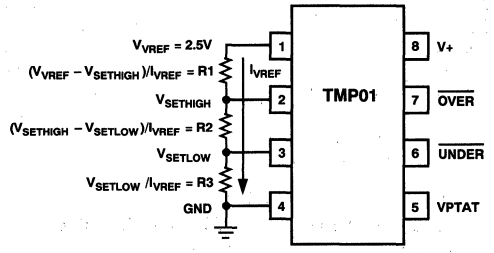

Figure 3. TMP01 Setpoint Programming

The total R1 + R2 + R3 is equal to the load resistance needed to draw the desired hysteresis current from the reference, or I_{VREF}.

The formulas shown above are also helpful in understanding the calculation of temperature setpoint voltages in circuits other than the standard two-temperature thermostat. If a setpoint function is not needed, the appropriate comparator should be disabled. SETHIGH can be disabled by tying it to V+, SETLOW by tying it to GND. Either output can be left unconnected.

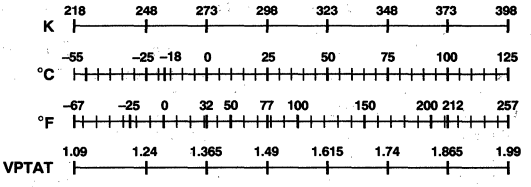

Figure 4. Temperature–VPTAT Scale

Understanding Error Sources

The accuracy of the VPTAT sensor output is well characterized and specified, however preserving this accuracy in a heating or cooling control system requires some attention to minimizing the various potential error sources. The internal sources of setpoint programming error include the initial tolerances and temperature drifts of the reference voltage VREF, the setpoint comparator input offset voltage and bias current, and the hysteresis current scale factor. When evaluating setpoint programming errors, remember that any VREF error contribution at the comparator inputs is reduced by the resistor divider ratios. The comparator input bias current (inputs SETHIGH, SETLOW) drops to less than 1 nA (typ) when the comparator is tripped. This can account for some setpoint voltage error, equal to the change in bias current times the effective setpoint divider ladder resistance to ground.

The thermal mass of the TMP01 package and the degree of thermal coupling to the surrounding circuitry are the largest factors in determining the rate of thermal settling, which ultimately determines the rate at which the desired temperature measurement accuracy may be reached. Thus, one must allow sufficient time for the device to reach the final temperature. The typical thermal time constant for the plastic package is approximately 140 seconds in still air! Therefore, to reach the final temperature accuracy within 1%, for a temperature change of 60 degrees, a settling time of 5 time constants, or 12 minutes, is necessary.

The setpoint comparator input offset voltage and zero hysteresis current affect setpoint error. While the 7 μA zero hysteresis current allows the user to program the TMP01 with moderate resistor divider values, it does vary somewhat from device to device, causing slight variations in the actual hysteresis obtained in practice. Comparator input offset directly impacts the programmed setpoint voltage and thus the resulting hysteresis band, and must be included in error calculations.

External error sources to consider are the accuracy of the external programming resistors, grounding error voltages, comparator input noise, comparator input bias current, and the overall problem of thermal gradients. The accuracy of the external programming resistors directly impacts the resulting setpoint accuracy. Thus in fixed-temperature applications the user should select resistor tolerances appropriate to the desired programming accuracy. Resistor temperature drift must be taken into account also. This effect can be minimized by selecting good quality components, and by keeping all components in close thermal proximity. Applications requiring high measurement accuracy require great attention to detail regarding thermal gradients. Careful circuit board layout, component placement, and protection from stray air currents are necessary to minimize common thermal error sources.

Also, the user should take care to keep the bottom of the setpoint programming divider ladder as close to GND (Pin 4) as possible to minimize errors due to IR voltage drops and coupling of external noise sources. In any case, a 0.1 μF capacitor for power supply bypassing is always recommended at the chip.

Safety Considerations In Heating And Cooling System Design

Designers should anticipate potential system fault conditions which may result in significant safety hazards which are outside the control of and cannot be corrected by the TMP01-based circuit. Governmental and industrial regulations regarding safety requirements and standards for such designs should be observed where applicable.

APPLICATIONS INFORMATION

Self-Heating Effects

In some applications the user should consider the effects of self-heating due to the power dissipated by the open-collector outputs, which are capable of sinking 20 mA continuously. Under full load, the TMP01 open-collector output device is dissipating

$$P_{DISS} = 0.6\ V \times .020A = 12\ mW$$

which in a surface-mount SO package accounts for a temperature increase due to self-heating of

$$\Delta T = P_{DISS} \times \theta_{JA} = .012\ W \times 158°C/W = 1.9°C.$$

This will of course directly affect the accuracy of the TMP01 and will for example cause the device to switch the heating output "OFF" 2 degrees early. Alternatively, bonding the same package to a moderate heatsink limits the self-heating effect to approximately

$$\Delta T = P_{DISS} \times \theta_{JC} = .012\ W \times 43°C/W = 0.52°C$$

which is a much more tolerable error in most systems. The VREF and VPTAT outputs are also capable of delivering sufficient current to contribute heating effects and should not be ignored.

Buffering the Voltage Reference

As mentioned above, the reference output VREF is used to generate the temperature setpoint programming voltages for the TMP01 and also is used to determine the hysteresis temperature band by the reference load current I_{VREF}. The on-board output buffer amplifier is typically capable of 500 μA output drive into as much as 50 pF load (max). Exceeding this load will affect the accuracy of the reference voltage, could cause thermal sensing errors due to dissipation, and may induce oscillations. Selection of a low drift buffer functioning as a voltage follower with high input impedance will ensure optimal reference accuracy, and will not affect the programmed hysteresis current. Amplifiers which offer the low drift, low power consumption, and low cost appropriate to this application include the OP295, and members of the OP90, OP97, OP177 families, and others as shown in the following applications circuits.

With excellent drift and noise characteristics, V_{REF} offers a good voltage reference for data acquisition and transducer excitation applications as well. Output drift is typically better than −10 ppm/°C, with 315 nV/$\sqrt{\text{Hz}}$ (typ) noise spectral density at 1 kHz.

Preserving Accuracy Over Wide Temperature Range Operation

The TMP01 is unique in offering both a wide-range temperature sensor and the associated detection circuitry needed to implement a complete thermostatic control function in one monolithic device. While the voltage reference, setpoint comparators, and output buffer amplifiers have been carefully compensated to maintain accuracy over the specified temperature range, the user has an additional task in maintaining the accuracy over wide operating temperature ranges in his application. Since the TMP01 is both sensor and control circuit, in many applications it is possible that the external components used to program and interface the device may be subjected to the same temperature extremes. Thus it may be necessary to locate components in close thermal proximity to minimize large temperature differentials, and to account for thermal drift errors where appropriate, such as resistor matching tempcos, amplifier error drift, and the like. Circuit design with the TMP01 requires a sightly different perspective regarding the thermal behavior of electronic components.

Thermal Response Time

The time required for a temperature sensor to settle to a specified accuracy is a function of the thermal mass of, and the thermal conductivity between the sensor and the object being sensed. Thermal mass is often considered equivalent to capacitance. Thermal conductivity is commonly specified using the symbol Q, and can be thought of as thermal resistance. It is commonly specified in units of degrees per watt of power transferred across the thermal joint. Thus, the time required for the TMP01 to settle to the desired accuracy is dependent on the package selected, the thermal contact established in that particular application, and the equivalent power of the heat source. In most applications, the settling time is probably best determined empirically.

Switching Loads With The Open-Collector Outputs

In many temperature sensing and control applications some type of switching is required. Whether it be to turn on a heater when the temperature goes below a minimum value or to turn off a motor that is overheating, the open-collector outputs Over and Under can be used. For the majority of applications, the switches used need to handle large currents on the order of 1 Amp and above. Because the TMP01 is accurately measuring temperature, the open-collector outputs should handle less than 20 mA of current to minimize self-heating. Clearly, the Overtemp and Undertemp outputs should not drive the equipment directly. Instead, an external switching device is required to handle the large currents. Some examples of these are relays, power MOSFETs, thyristors, IGBTs, and Darlingtons.

Figure 15 shows a variety of circuits where the TMP01 controls a switch. The main consideration in these circuits, such as the relay in Figure 15a, is the current required to activate the switch.

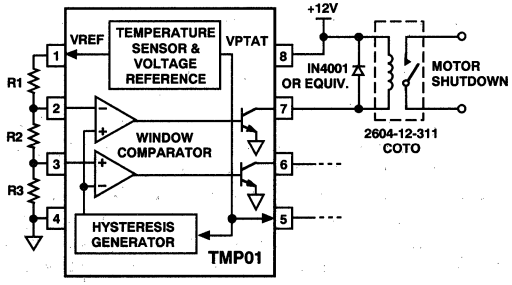

Figure 15a. Reed Relay Drive

It is important to check the particular relay you choose to ensure that the current needed to activate the coil does not exceed the TMP01's recommended output current of 20 mA. This is easily determined by dividing the relay coil voltage by the specified coil resistance. Keep in mind that the inductance of the relay will create large voltage spikes that can damage the TMP01 output unless protected by a commutation diode across the coil, as shown. The relay shown has a contact rating of 10 watts maximum. If a relay capable of handling more power is desired, the larger contacts will probably require a commensurately larger coil, with lower coil resistance and thus higher trigger current. As the contact power handling capability increases, so does the current needed for the coil. In some cases an external driving transistor should be used to remove the current load on the TMP01 as explained in the next section.

Power FETs are popular for handling a variety of high current DC loads. Figure 15b shows the TMP01 driving a p-channel MOSFET transistor for a simple heater circuit. When the output transistor turns on, the gate of the MOSFET is pulled down to approximately 0.6 V, turning it on. For most MOSFETs a gate-to-source voltage or Vgs on the order of −2 V to −5 V is sufficient to turn the device on. Figure 15c shows a similar circuit for turning on an n-channel MOSFET, except that now the gate to source voltage is positive. Because of this reason an external transistor must be used as an inverter so that the MOSFET will turn on when the "Under Temp" output pulls down.

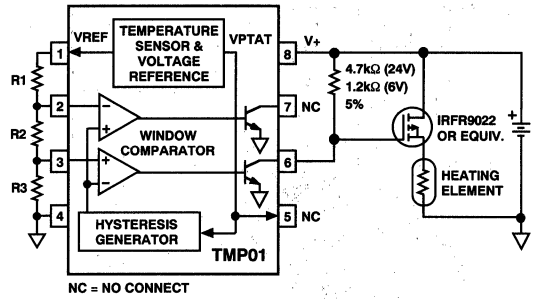

Figure 15b. Driving a P-Channel MOSFET

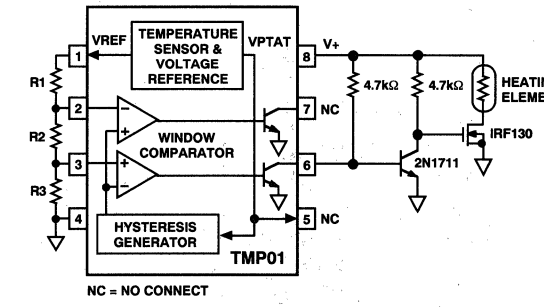

Figure 15c. Driving a N-Channel MOSFET

Isolated Gate Bipolar Transistors (IGBT) combine many of the benefits of power MOSFETs with bipolar transistors, and are used for a variety of high power applications. Because IGBTs have a gate similar to MOSFETs, turning on and off the devices is relatively simple as shown in Figure 15d. The turn on voltage for the IGBT shown (IRGBC40S) is between 3.0 and 5.5 volts. This part has a continuous collector current rating of 50 A and a maximum collector to emitter voltage of 600 V, enabling it to work in very demanding applications.

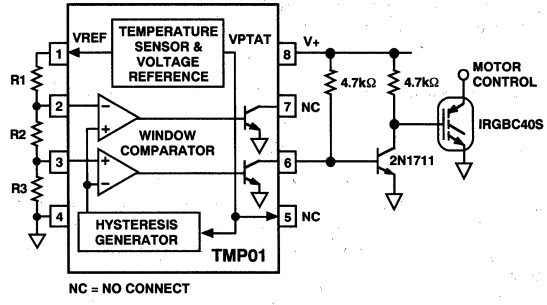

Figure 15d. Driving an IGBT

The last class of high power devices discussed here are Thyristors, which includes SCRs and Triacs. Triacs are a useful alternative to relays for switching ac line voltages. The 2N6073A shown in Figure 15e is rated to handle 4A (rms). The opto-isolated MOC3021 Triac shown features excellent electrical isolation from the noisy ac line and complete control over the high power Triac with only a few additional components.

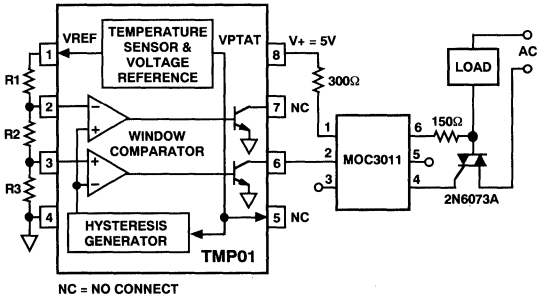

Figure 15e. Controlling the 2N6073A Triac

High Current Switching

As mentioned above, internal dissipation due to large loads on the TMP01 outputs will cause some temperature error due to self-heating. External transistors remove the load from the TMP01, so that virtually no power is dissipated in the internal transistors and no self-heating occurs. Figure 16 shows a few examples using external transistors. The simplest case, using a single transistor on the output to invert the output signal is shown in Figure 16a. When the open-collector of the TMP01 turns "ON" and pulls the output down, the external transistor Q1's base will be pulled low, turning off the transistor. Another transistor can be added to reinvert the signal as shown in Figure 16b. Now, when the output of the TMP01 is pulled down, the first transistor, Q1, turns off and its collector goes high, which turns Q2 on, pulling its collector low. Thus, the output taken from the collector of Q2 is identical to the output of the TMP01. By picking a transistor that can accommodate large amounts of current, many high power devices can be switched.

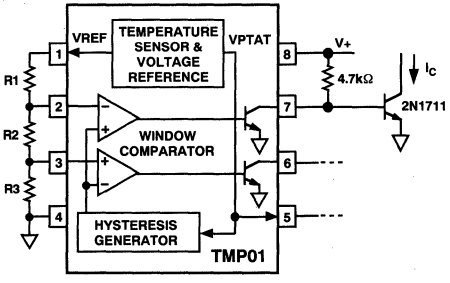

Figure 16a. An External Resistor Minimizes Self-Heating

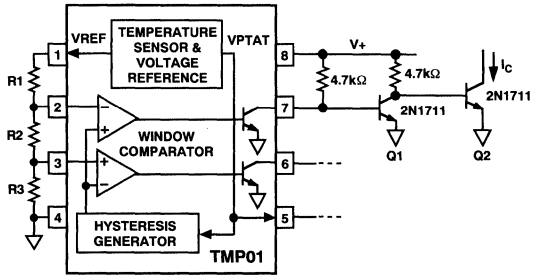

Figure 16b. Second Transistor Maintains Polarity of TMP01 Output

An example of a higher power transistor is a standard Darlington configuration as shown in Figure 16c. The part chosen, TIP-110, can handle 2A continuous which is more than enough to control many high power relays. In fact the Darlington itself can be used as the switch, similar to MOSFETs and IGBTs.

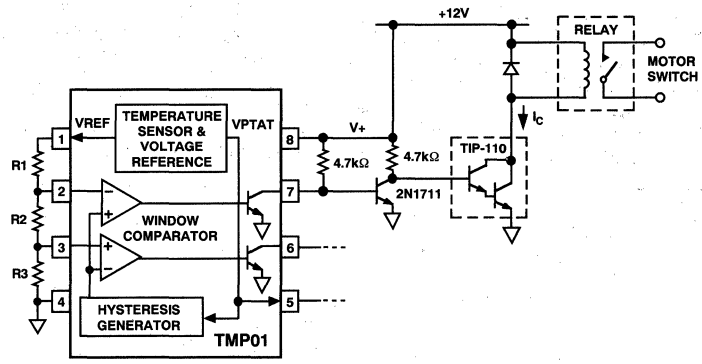

Figure 16c. Darlington Transistor Can Handle Large Currents

Buffering the Temperature Output Pin

The VPTAT sensor output is a low impedance dc output voltage with a 5 mV/K temperature coefficient, and is useful in a number of measurement and control applications. In many applications, this voltage needs to be transmitted to a central location for processing. The buffered VPTAT voltage output is capable of 500 μA drive into 50 pF (max). As mentioned in the discussion above regarding buffering circuits for the VREF output, it is useful to consider external amplifiers for interfacing VPTAT to external circuitry to ensure accuracy, and to minimize loading which could create dissipation-induced temperature sensing errors. An excellent general-purpose buffer circuit using the OP177 is shown in Figure 17 which is capable of driving over 10 mA, and will remain stable under capacitive loads of up to 0.1 μF. Other interfacing ideas are shown below.

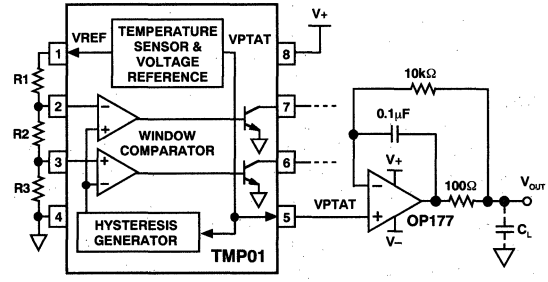

Figure 17. Buffer VPTAT to Handle Difficult Loads

Differential Transmitter

In noisy industrial environments, it is difficult to send an accurate analog signal over a significant distance. However, by sending the signal differentially on a wire pair, these errors can be significantly reduced. Since the noise will be picked up equally on both wires, a receiver with high common-mode input rejection can be used to cancel out the noise very effectively at the receiving end. Figure 18 shows two amplifiers being used to send the signal differentially, and an excellent differential receiver, the AMP03, which features a common mode rejection ratio of 95 dB at dc and very low input and drift errors.

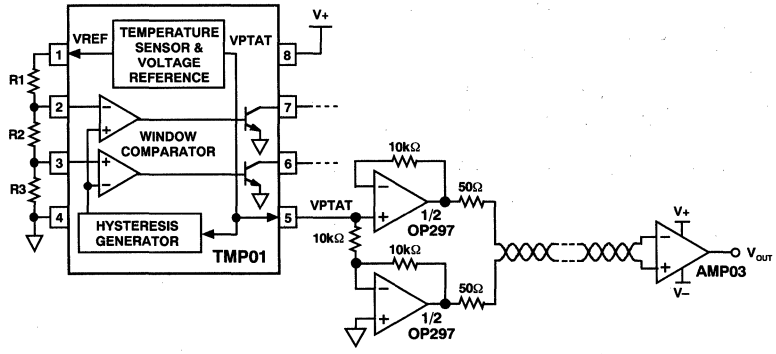

Figure 18. Send the Signal Differentially for Noise Immunity

4 mA–20 mA Current Loop

Another, very common method of transmitting a signal over long distances is to use a 4 mA–20 mA Loop, as shown in Figure 19. An advantage of using a 4 mA–20 mA loop is that the accuracy of a current loop is not compromised by voltage drops across the line. One requirement of 4 mA–20 mA circuits is that the remote end must receive all of its power from the loop, meaning that the circuit must consume less than 4 mA. Operating from +5 V, the quiescent current of the TMP01 is 500 μA max, and the OP90's is 20 μA max, totaling less than 4 mA. Although not shown, the open collector outputs and temperature setting pins can be connected to do any local control of switching.

The current is proportional to the voltage on the VPTAT output, and is calibrated to 4 mA at a temperature of −40°C, to 20 mA for +85°C. The main equation governing the operation of this circuit gives the current as a function of VPTAT:

$$I_{OUT} = \frac{1}{R_6}\left(\frac{VPTAT \times R_5}{R_2} - \frac{VREF \times R_3}{R_3 + R_1}\left(1 + \frac{R_5}{R_2}\right)\right)$$

The resulting temperature coefficient of the output current is 128 μA/°C.

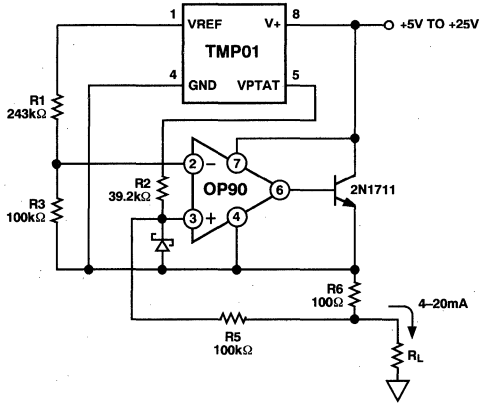

Figure 19. 4–20 mA Current Loop

To determine the resistor values in this circuit, first note that VREF remains constant over temperature. Thus the ratio of R5 over R2 must give a variation of I_{OUT} from 4 mA to 20 mA as VPTAT varies from 1.165 V at −40°C to 1.79 V at +85°C. The absolute value of the resistors is not important, only the ratio. For convenience, 100 kΩ is chosen for R5. Once R2 is calculated, the value of R3 and R1 is determined by substituting 4 mA for I_{OUT} and 1.165 V for VPTAT and solving. The final values are shown in the circuit. The OP90 is chosen for this circuit because of its ability to operate on a single supply and its high accuracy. For initial accuracy, a 10 kΩ trim potentiometer can be included in series with R3, and the value of R3 lowered to 95 kΩ. The potentiometer should be adjusted to produce an output current of 12.3 mA at 25°C.

Temperature-to-Frequency Converter

Another common method of transmitting analog information is to convert a voltage to the frequency domain. This is easily done with any of the low cost monolithic Voltage-to-Frequency Converters (VFCs) available, which feature a robust, open-collector digital output. A digital signal is very immune to noise and voltage drops because the only important information is the frequency. As long as the conversions between temperature and frequency are done accurately, the temperature data can be successfully transmitted.

A simple circuit to do this combines the TMP01 with an AD654 VFC, as shown in Figure 20. The AD654 outputs a square wave that is proportional to the dc input voltage according to the following equation:

$$F_{OUT} = \frac{V_{IN}}{10\,(R_1 + R_2)\,C_T}$$

By simply connecting the VPTAT output to the input of the AD654, the 5 mV/°C temperature coefficient gives a sensitivity of 25 Hz/°C, centered around 7.5 kHz at 25°C. The trimming resistor R2 is needed to calibrate the absolute accuracy of the AD654. For more information on that part, please consult the AD654 data sheet. Finally, the AD650 can be used to accurately convert the frequency back to a dc voltage on the receiving end.

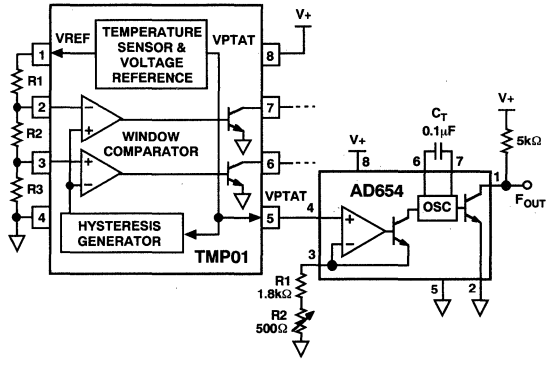

Figure 20. Temperature-to-Frequency Converter

Isolation Amplifier

In many industrial applications the sensor is located in an environment that needs to be electrically isolated from the central processing area. Figure 21 shows a simple circuit that uses an 8-pin optoisolator (IL300XC) that can operate across a 5,000 V barrier. IC1 (an OP290 single-supply amplifier) is used to drive the LED connected between Pins 1 to 2. The feedback actually

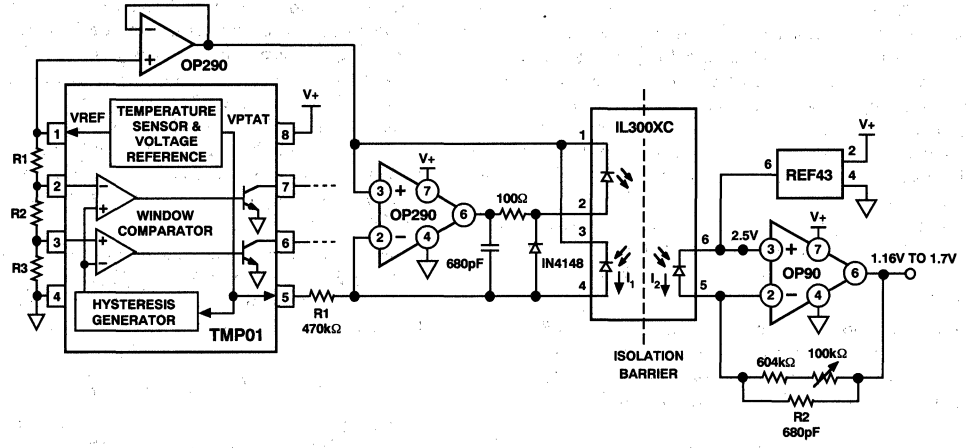

Figure 21. Isolation Amplifier

comes from the photodiode connected from Pins 3 to 4. The OP290 drives the LED such that there is enough current generated in the photodiode to exactly equal the current derived from the VPTAT voltage across the 470 kΩ resistor. On the receiving end, an OP90 converts the current from the second photodiode to a voltage through its feedback resistor R2. Note that the other amplifier in the dual OP290 is used to buffer the 2.5 V reference voltage of the TMP01 for an accurate, low drift LED bias level without affecting the programmed hysteresis current. A REF43 (a precision 2.5 V reference) provides an accurate bias level at the receiving end.

To understand this circuit, it helps to examine the overall equation for the output voltage. First, the current (I1) in the photodiode is set by:

$$I_1 = \frac{2.5\ V - VPTAT}{470\ k\Omega}$$

Note that the IL300XC has a gain of 0.73 (typical) with a min and max of 0.693 and 0.769 respectively. Since this is less than 1.0, R2 must be larger than R1 to achieve overall unity gain. To show this the full equation is:

$$V_{OUT} = 2.5\ V - I_2R_2 = 2.5\ V - 0.7\left(\frac{2.5\ V - VPTAT}{470\ k\Omega}\right) 644\ k\Omega = VPTAT$$

A trim is included for R2 to correct for the initial gain accuracy of the IL300XC. To perform this trim, simply adjust for an output voltage equal to VPTAT at any particular temperature. For example, at room temperature, VPTAT = 1.49 V, so adjust R2 until V_{OUT} = 1.49 V as well. Both the REF43 and the OP90 operate from a single supply, and contribute no significant error due to drift.

In order to avoid the accuracy trim, and to reduce board space, complete isolation amplifiers are available, such as the high accuracy AD202.

Out-of-Range Warning

By connecting the two open collector outputs of the TMP01 together into a "wired-OR" configuration, a temperature "out-of-range" warning signal is generated. This can be useful in sensitive equipment calibrated to work over a limited temperature range. R1, R2, and R3 in Figure 22 are chosen to give a temperature range of 10°C around room temperature (25°C). Thus, if the temperature in the equipment falls below +15°C or rises above +35°C, the Undertemp Output or Overtemp Output

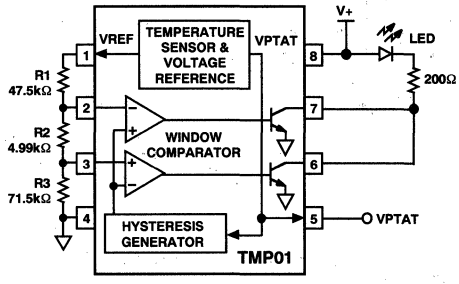

Figure 22. Out-of-Range Warning

respectively will go low and turn the LED on. The LED may be replaced with a simple pull-up resistor to give a logic output for controlling the instrument, or any of the switching devices discussed above can be used.

Translating 5 mV/K to 10 mV/°C

A useful circuit is shown in Figure 23 that translates the VPTAT output voltage, which is calibrated in Kelvins, into an output that can be read directly in degrees Celsius on a voltmeter display. To accomplish this, an external amplifier is configured as a differential amplifier. The resistors are scaled so the VREF voltage will exactly cancel the VPTAT voltage at 0.0°C.

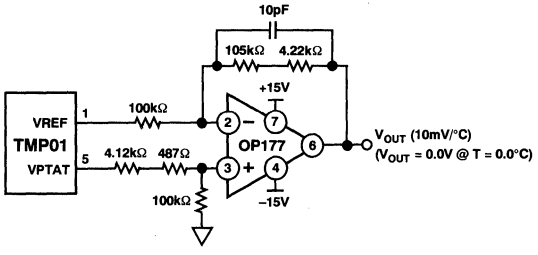

Figure 23. Translating 5 mV/K to 10 mV/°C

However, the gain from VPTAT to the output is two, so that 5 mV/K becomes 10 mV/°C. Thus, for a temperature of +80°C, the output voltage is 800 mV. Circuit errors will be due primarily to the inaccuracies of the resistor values. Using 1% resistors the observed error was less than 10 mV, or 1°C. The 10 pF feedback capacitor helps to ensure against oscillations. For better accuracy, a adjustment potentiometer can be added in series with either 100 kΩ resistor.

Translating VPTAT to the Fahrenheit Scale

A very similar circuit to the one shown in Figure 23 can be used to translate VPTAT into an output that can be read directly in degrees Fahrenheit, with a scaling of 10 mV/°F. Only unity gain or less is available from the first stage differentiating circuit, so the second amplifier provides a gain of two to complete the conversion to the Fahrenheit scale. Using the circuit in Figure 24, a temperature of 0.0°F gives an output of 0.00 V. At room temperature (70°F) the output voltage is 700 mV. A −40°C to +85°C operating range translates into −40°F to +185°F. The errors are essentially the same as for the circuit in Figure 23.

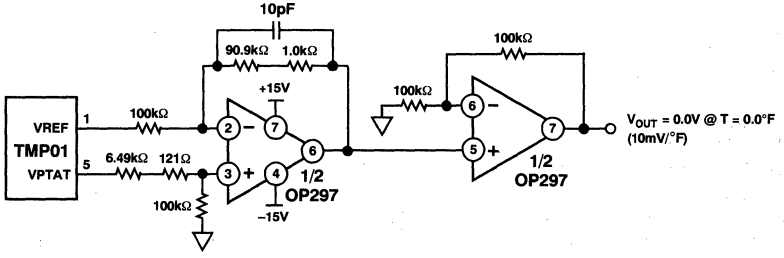

Figure 24. Translating 5 mV/K to 10 mV/°F

ANALOG DEVICES

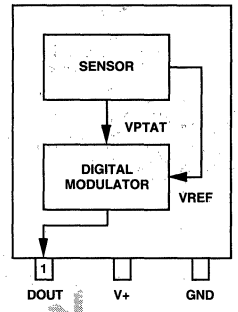
Micropower Temperature Peripheral

TMP03/TMP03L*

FEATURES
Modulated Serial Digital Output Proportional to Temperature
±1.2°C Accuracy Over Temperature (typ)
Specified -40°C to +100°C, Operation to 150°C
Power Consumption 3.5 mW at 5 V
No External Components
Flexible Open Collector Output (TMP03)
CMOS/TTL Compatible Output on TMP03L
Low Voltage Operation (4.5 V to 7 V)
Low Cost 3-Pin Packages

APPLICATIONS
Isolated Sensors
Environmental Control Systems
Thermal Protection
Industrial Process Control
Power System Monitors

FUNCTIONAL BLOCK DIAGRAM



GENERAL DESCRIPTION

The TMP03/TMP03L is a monolithic temperature detector that generates a modulated serial digital output which varies in direct proportion to the temperature of the device. An onboard sensor generates a voltage precisely proportional to absolute temperature which is input to a precision digital modulator. The ratiometric encoding format of the serial digital output is independent of the clock drift errors common to most serial modulation techniques such as voltage-to-frequency converters. Overall accuracy is ±1.2 degrees (typical) over the rated operating temperature range, with excellent transducer linearity. The digital output of the TMP03L is CMOS/TTL compatible and is easily interfaced to the serial inputs of most popular microprocessors. The open collector output of the TMP03 is capable of sinking 20 mA and is suitable for industrial systems including isolated circuits utilizing opto-couplers or isolation transformers.

The TMP03 and the TMP03L are specified for operation at supply voltages from 4.5 V to 7 V. Operating from +5 V, supply current (unloaded) is less than 700 µA (max).

The TMP03/TMP03L is rated for operation over the -40°C to +100°C temperature range in the low cost TO-92, and SO-8 and TSSOP-8 surface mount packages. Operation extends to 150°C with reduced accuracy.

GENERAL DESCRIPTION *(continued)*

The TMP03/TMP03L is a powerful, complete temperature measurement system with digital output, on a single chip. The onboard temperature sensor follows in the footsteps of the TMP01 low power, programmable temperature controller, offering excellent accuracy and linearity over the entire rated temperature range without correction or calibration by the user.

The sensor output is digitized by an advanced first order sigma-delta modulator, also known as the "charge balance" type analog-to-digital converter. See Figure 1. This type of converter utilizes time domain oversampling and a high accuracy comparator to deliver 12 bits of effective accuracy in an extremely compact circuit

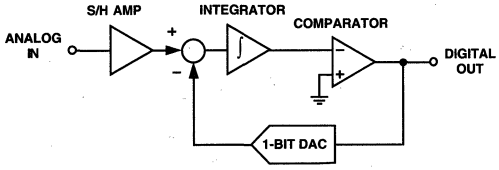

Figure 1. First-Order Sigma-Delta Modulator

Basically, the sigma-delta modulator consists of an input sample-and-hold, a summing amplifier, an integrator, a comparator, and a 1-bit DAC. Similar to the voltage-to-frequency converter, this architecture creates in effect a negative feedback loop whose intent is to minimize the integrator output by changing the duty cycle of the comparator output in response to input voltage changes. The comparator samples the output of the integrator at a much higher rate than the input sampling frequency, called oversampling. This spreads the quantization noise over a much wider band than that of the input signal, improving overall noise performance and increasing accuracy.

The modulated output of the comparator is encoded using a patented technique which results in a serial digital signal with a ratiometric duty cycle format which is easily decoded by any microprocessor into either degrees Centigrade or degrees Fahrenheit values, and readily transmitted or modulated over a single wire. Most importantly, this encoding method neatly avoids major error sources common to other modulation techniques, as it is clock independent.

Output Encoding

Accurate sampling of an analog signal requires precise spacing of the sampling interval in order to maintain an accurate representation of the signal in the time domain. This dictates a master clock between the digitizer and the signal processor. In the case of compact, cost-effective data acquisition systems, the addition of a buffered high speed clock line can represent a significant burden on the overall system design. Alternatively, the addition of an onboard clock circuit with the appropriate accuracy and drift performance to an integrated circuit can add significant cost. The modulation and encoding techniques utilized in the TMP03/TMP03L avoid this problem and allow the overall circuit to fit into a compact, three-pin package. To achieve this, a simple, compact onboard clock and an oversampling digitizer which is insensitive to sampling rate variations are used.

Most importantly, the digitized signal is encoded into a ratiometric format in which the exact frequency of the TMP03/TMP03L's clock is irrelevant, and the effects of clock variations at the counter are effectively cancelled upon decoding.

The output of the TMP03/TMP03L is a square wave with a nominal frequency of 45 Hz. The output format is readily decoded by the user as follows:

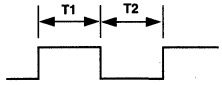

Figure 2. TMP03/TMP03L Output Format

$$Temperature\,(°C) = 260 - \left(\frac{450 \times T1}{T2}\right)$$

$$Temperature\,(°F) = 500 - \left(\frac{810 \times T1}{T2}\right)$$

where the time period T1 (low period) and T2 (high period) are counter values easily read by a microprocessor input port, and the above calculations performed in software. Since both periods are obtained consecutively, using the same clock, performing the division indicated in the above formulas results in a ratiometric value that is independent of the exact frequencies of, or drift in, either the originating clock of the TMP03 or the user's counting clock.

A period counting clock of approximately 1 MHz (or higher) will provide sufficient resolution to maintain the specified measurement accuracy of the TMP03/TMP03L. While a system running a 1 MHz clock will require counter registers of at least 12 bits, faster clocks will require commensurately larger registers to avoid overflow truncation errors. See the Applications section below which discusses a variety of hardware interfacing and software ideas.

Self-Heating Effects

Observing the thermal conductivity of the various TMP03/TMP03L packages, in some applications the user should consider the effects of self-heating due to the power dissipated by the digital output, which is capable of sinking 800 µA continuous. Under full load, the output may dissipate

$$P_{DISS} = (0.6\,V)(0.8\,mA) = 0.48\,mW$$

which in a free-standing surface-mount TSSOP package accounts for a temperature increase due to self-heating of

$$\Delta T = P_{DISS} \times \theta_{JA} = 0.48\,mW \times XXX\,°C/W = YY°C.$$

This will, of course, directly affect the accuracy of the TMP03/TMP03L relative to the true ambient temperature. Alternatively, when the same package has been bonded to measure a large plate or other thermal mass (effectively a large heatsink), the self-heating error might be limited to approximately

$$\Delta T = P_{DISS} \times \theta_{JC} = 0.48\,mW \times 10°C/W = 0.0048°C$$

which is a negligible error.

ANALOG DEVICES

Dual, Low Noise, Wideband Variable Gain Amplifiers

AD600/AD602*

FEATURES

Two Channels with Independent Gain Control
"Linear in dB" Gain Response
Two Gain Ranges:
AD600: 0 dB to +40 dB
AD602: −10 dB to +30 dB
Accurate Absolute Gain: ±0.3 dB
Low Input Noise: 1.4 nV/√Hz
Low Distortion: −60 dBc THD at ±1 V Output
High Bandwidth: DC to 35 MHz (−3 dB)
Stable Group Delay: ±2 ns
Low Power: 125 mW (max) per Amplifier
Signal Gating Function for Each Amplifier
Drives High Speed A/D Converters
MIL-STD-883 Compliant and DESC Versions Available

APPLICATIONS

Ultrasound and Sonar Time-Gain Control
High Performance Audio and RF AGC Systems
Signal Measurement

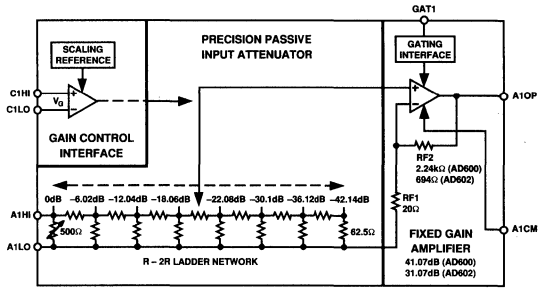
PRODUCT DESCRIPTION

The AD600 and AD602 dual channel, low noise variable gain amplifiers are optimized for use in ultrasound imaging systems, but are applicable to any application requiring very precise gain, low noise and distortion, and wide bandwidth. Each independent channel provides a gain of 0 to +40 dB in the AD600 and −10 dB to +30 dB in the AD602. The lower gain of the AD602 results in an improved signal-to-noise ratio at the output. However, both products have the same 1.4 nV/√Hz input noise spectral density. The decibel gain is directly proportional to the control voltage, is accurately calibrated, and is supply- and temperature-stable.

To achieve the difficult performance objectives, a proprietary circuit form—the X-AMP™—has been developed. Each channel of the X-AMP comprises a variable attenuator of 0 dB to −42.14 dB followed by a high speed fixed gain amplifier. In this way, the amplifier never has to cope with large inputs, and can benefit from the use of negative feedback to precisely define the gain and dynamics. The attenuator is realized as a seven-stage R-2R ladder network having an input resistance of 100 Ω, laser-trimmed to ±2%. The attenuation between tap points is 6.02 dB; the gain-control circuit provides continuous interpolation between these taps. The resulting control function is linear in dB.

X-AMP is a trademark of Analog Devices, Inc.
*Patented.

FUNCTIONAL BLOCK DIAGRAM



The gain-control interfaces are fully differential, providing an input resistance of ~15 MΩ and a scale factor of 32 dB/V (that is, 31.25 mV/dB) defined by an internal voltage reference. The response time of this interface is less than 1 μs. Each channel also has an independent gating facility that optionally blocks signal transmission and sets the dc output level to within a few millivolts of the output ground. The gating control input is TTL and CMOS compatible.

The maximum gain of the AD600 is 41.07 dB, and that of the AD602 is 31.07 dB; the −3 dB bandwidth of both models is nominally 35 MHz, essentially independent of the gain. The signal-to-noise ratio (SNR) for a 1 V rms output and a 1 MHz noise bandwidth is typically 76 dB for the AD600 and 86 dB for the AD602. The amplitude response is flat within ±0.5 dB from 100 kHz to 10 MHz; over this frequency range the group delay varies by less than ±2 ns at all gain settings.

Each amplifier channel can drive 100 Ω load impedances with low distortion. For example, the peak specified output is ±2.5 V minimum into a 500 Ω load, or ±1 V into a 100 Ω load. For a 200 Ω load in shunt with 5 pF, the total harmonic distortion for a ±1 V sinusoidal output at 10 MHz is typically −60 dBc.

The AD600J and AD602J are specified for operation from 0°C to +70°C, and are available in both 16-pin plastic DIP (N) and 16-pin SOIC (R). The AD600A and AD602A are specified for operation from −40°C to +85°C and are available in both 16-pin Cerdip (Q) and 16-pin SOIC (R).

The AD600S and AD602S are specified for operation from −55°C to +125°C and are available in a 16-pin Cerdip (Q) package and are MIL-STD-883 compliant. The AD600S and AD602S are also available under DESC SMD 5962-94572.

NOTES

[1]Typical open or short-circuited input; noise is lower when system is set to maximum gain and input is short-circuited. This figure includes the effects of both voltage and current noise sources.

[2]Using resistive loads of 500 Ω or greater, or with the addition of a 1 kΩ pull-down resistor when driving lower loads.

[3]The dc gain of the main amplifier in the AD600 is X113; thus an input offset of only 100 μV becomes an 11.3 mV output offset. In the AD602, the amplifier's gain is X35.7; thus, an input offset of 100 μV becomes a 3.57 mV output offset.

Specifications shown in **boldface** are tested on all production units at final electrical test. Results from those tests are used to calculate outgoing quality levels. All min and max specifications are guaranteed, although only those shown in boldface are tested on all production units.

Specifications subject to change without notice.

ABSOLUTE MAXIMUM RATINGS[1]

Supply Voltage $\pm V_S$ . . . . . ±7.5 V

CAUTION

ESD (electrostatic discharge) sensitive device. Permanent damage may occur on unconnected devices subject to high energy electrostatic fields. Unused devices must be stored in conductive foam or shunts. The protective foam should be discharged to the destination socket before devices are removed.

PIN DESCRIPTIONS

Pin	Function	Description
Pin 1	C1LO	CH1 Gain-Control Input "LO" (Positive Voltage Reduces CH1 Gain).
Pin 2	A1HI	CH1 Signal Input "HI" (Positive Voltage Increases CH1 Output).
Pin 3	A1LO	CH1 Signal Input "LO" (Usually Taken to CH1 Input Ground).
Pin 4	GAT1	CH1 Gating Input (A Logic "HI" Shuts Off CH1 Signal Path).
Pin 5	GAT2	CH2 Gating Input (A Logic "HI" Shuts Off CH2 Signal Path).
Pin 6	A2LO	CH2 Signal Input "LO" (Usually Taken to CH2 Input Ground).
Pin 7	A2HI	CH2 Signal Input "HI" (Positive Voltage Increases CH2 Output).
Pin 8	C2LO	CH2 Gain-Control Input "LO" (Positive Voltage Reduces CH2 Gain).
Pin 9	C2HI	CH2 Gain-Control Input "HI" (Positive Voltage Increases CH2 Gain).
Pin 10	A2CM	CH2 Common (Usually Taken to CH2 Output Ground).
Pin 11	A2OP	CH2 Output.
Pin 12	VNEG	Negative Supply for Both Amplifiers.
Pin 13	VPOS	Positive Supply for Both Amplifiers.
Pin 14	A1OP	CH1 Output.
Pin 15	A1CM	CH1 Common (Usually Taken to CH1 Output Ground).
Pin 16	C1HI	CH1 Gain-Control Input "HI" (Positive Voltage Increases CH1 Gain).

THEORY OF OPERATION

The AD600 and AD602 have the same general design and features. They comprise two fixed gain amplifiers, each preceded by a voltage-controlled attenuator of 0 dB to 42.14 dB with independent control interfaces, each having a scaling factor of 32 dB per volt. The gain of each amplifier in the AD600 is laser trimmed to 41.07 dB (X113), thus providing a control range of −1.07 dB to 41.07 dB (0 dB to 40 dB with overlap), while the AD602 amplifiers have a gain of 31.07 dB (X35.8) and provide an overall gain of −11.07 dB to 31.07 dB (−10 dB to 30 dB with overlap).

The advantage of this topology is that the amplifier can use negative feedback to increase the accuracy of its gain; also, since the amplifier never has to handle large signals at its input, the distortion can be very low. A further feature of this approach is that the small-signal gain and phase response, and thus the pulse response, are essentially independent of gain.

The following discussion describes the AD600. Figure 1 is a simplified schematic of one channel. The input attenuator is a seven-section R-2R ladder network, using untrimmed resistors of nominally R = 62.5 Ω, which results in a characteristic resistance of 125 Ω ±20%. A shunt resistor is included at the input and laser trimmed to establish a more exact input resistance of 100 Ω ±2%, which ensures accurate operation (gain and HP corner frequency) when used in conjunction with external resistors or capacitors.

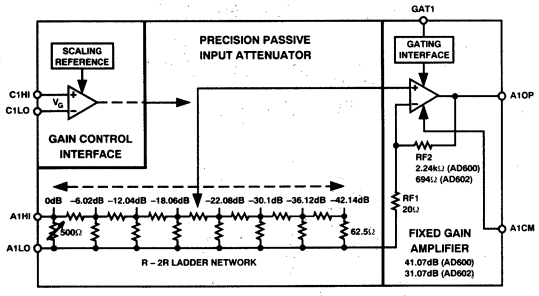

Figure 1. Simplified Block Diagram of Single Channel of the AD600 and AD602

The nominal maximum signal at input A1HI is 1 V rms (±1.4 V peak) when using the recommended ±5 V supplies, although operation to ±2 V peak is permissible with some increase in HF distortion and feedthrough. Each attenuator is provided with a separate signal "LO" connection, for use in rejecting common-mode, the voltage between input and output grounds. Circuitry is included to provide rejection of up to ±100 mV.

The signal applied at the input of the ladder network is attenuated by 6.02 dB by each section; thus, the attenuation to each of the taps is progressively 0, 6.02, 12.04, 18.06, 24.08, 30.1, 36.12 and 42.14 dB. A unique circuit technique is employed to interpolate between these tap points, indicated by the "slider" in Figure 1, providing continuous attenuation from 0 dB to 42.14 dB. It will help, in understanding the AD600, to think in terms of a mechanical means for moving this slider from left to right; in fact, it is voltage controlled. The details of the control interface are discussed later. Note that the gain is at all times exactly determined, and a linear decibel relationship is automatically guaranteed between the gain and the control parameter which determines the position of the slider. In practice, the gain deviates from the ideal law, by about ±0.2 dB peak (see, for example, Figure 6).

Note that the signal inputs are not fully differential: A1LO and A1CM (for CH1) and A2LO and A2CM (for CH2) provide separate access to the input and output grounds. This recognizes the practical fact that even when using a ground plane, small differences will arise in the voltages at these nodes. It is important that A1LO and A2LO be connected directly to the input ground(s); significant impedance in these connections will reduce the gain accuracy. A1CM and A2CM should be connected to the load ground(s).

Noise Performance

An important reason for using this approach is the superior noise performance that can be achieved. The nominal resistance seen at the inner tap points of the attenuator is 41.7 Ω (one third of 125 Ω), which exhibits a Johnson noise spectral density (NSD) of 0.84 nV/$\sqrt{\text{Hz}}$ (that is, $\sqrt{4kTR}$) at 27°C, which is a large fraction of the total input noise. The first stage of the amplifier contributes a further 1.12 nV/$\sqrt{\text{Hz}}$, for a total input noise of 1.4 nV/$\sqrt{\text{Hz}}$.

The noise at the 0 dB tap depends on whether the input is short-circuited or open-circuited: when shorted, the minimum NSD of 1.12 nV/$\sqrt{\text{Hz}}$ is achieved; when open, the resistance of 100 Ω at the first tap generates 1.29 nV/$\sqrt{\text{Hz}}$, so the noise increases to a total of 1.71 nV/$\sqrt{\text{Hz}}$. (This last calculation would be important if the AD600 were preceded, for example, by a 900 Ω resistor to allow operation from inputs up to ±10 V rms. However, in most cases the low impedance of the source will limit the maximum noise resistance.)

It will be apparent from the foregoing that it is essential to use a low resistance in the design of the ladder network to achieve low noise. In some applications this may be inconvenient, requiring the use of an external buffer or preamplifier. However, very few amplifiers combine the needed low noise with low distortion at maximum input levels, and the power consumption needed to achieve this performance is fundamentally required to be quite high (due to the need to maintain very low resistance values while also coping with large inputs). On the other hand, there is little value in providing a buffer with high input impedance, since the usual reason for this—the minimization of loading of a high resistance source—is not compatible with low noise.

Apart from the small variations just discussed, the signal-to-noise (S/N) ratio at the output is essentially independent of the attenuator setting, since the maximum undistorted output is 1 V rms and the NSD at the output of the AD600 is fixed at 113 times 1.4 nV/$\sqrt{\text{Hz}}$, or 158 nV/$\sqrt{\text{Hz}}$. Thus, in a 1 MHz bandwidth, the output S/N ratio would be 76 dB. The input NSD of the AD600 and AD602 are the same, but because of the 10 dB lower gain in the AD602's fixed amplifier, its output S/N ratio is 10 dB better, or 86 dB in a 1 MHz bandwidth.

The Gain-Control Interface

The attenuation is controlled through a differential, high impedance (15 MΩ) input, with a scaling factor which is laser trimmed to 32 dB per volt, that is, 31.25 mV/dB. Each of the two amplifiers has its own control interface. An internal bandgap reference ensures stability of the scaling with respect to supply and temperature variations, and is the only circuitry common to both channels.

When the differential input voltage V_G = 0 V, the attenuator "slider" is centered, providing an attenuation of 21.07 dB, thus resulting in an overall gain of 20 dB (= −21.07 dB + 41.07 dB). When the control input is −625 mV, the gain is lowered by 20 dB (= 0.625 × 32), to 0 dB; when set to +625 mV, the gain is increased by 20 dB, to 40 dB. When this interface is overdriven in either direction, the gain approaches either −1.07 dB (= −42.14 dB + 41.07 dB) or 41.07 dB (= 0 + 41.07 dB), respectively.

The gain of the AD600 can thus be calculated using the following simple expression:

$$Gain\ (dB) = 32\ V_G + 20 \quad (1)$$

where V_G is in volts. For the AD602, the expression is:

$$Gain\ (dB) = 32\ V_G + 10 \quad (2)$$

Operation is specified for V_G in the range from −625 mV dc to +625 mV dc. The high impedance gain-control input ensures minimal loading when driving many amplifiers in multiple-channel applications. The differential input configuration provides flexibility in choosing the appropriate signal levels and polarities for various control schemes.

For example, the gain-control input can be fed differentially to the inputs, or single-ended by simply grounding the unused input. In another example, if the gain is to be controlled by a DAC providing a positive only ground referenced output, the "Gain Control LO" pin (either C1LO or C2LO) should be biased to a fixed offset of +625 mV, to set the gain to 0 dB when "Gain Control HI" (C1HI or C2HI) is at zero, and to 40 dB when at +1.25 V.

It is a simple matter to include a voltage divider to achieve other scaling factors. When using an 8-bit DAC having a FS output of +2.55 V (10 mV/bit) a divider ratio of 1.6 (generating 6.25 mV/bit) would result in a gain setting resolution of 0.2 dB/bit. Later, we will discuss how the two sections of an AD600 or AD602 may be cascaded, when various options exist for gain control.

Signal-Gating Inputs

Each amplifier section of the AD600 and AD602 is equipped with a signal gating function, controlled by a TTL or CMOS logic input (GAT1 or GAT2). The ground references for these inputs are the signal input grounds A1LO and A2LO, respectively. Operation of the channel is unaffected when this input is LO or left open-circuited. Signal transmission is blocked when this input is HI. The dc output level of the channel is set to within a few millivolts of the output ground (A1CM or A2CM), and simultaneously the noise level drops significantly. The reduction in noise and spurious signal feedthrough is useful in ultrasound beam-forming applications, where many amplifier outputs are summed.

Common-Mode Rejection

A special circuit technique is used to provide rejection of voltages appearing between input grounds (A1LO and A2LO) and output grounds (A1CM and A2CM). This is necessary because of the "op amp" form of the amplifier, as shown in Figure 1. The feedback voltage is developed across the resistor RF1 (which, to achieve low noise, has a value of only 20 Ω). The voltage developed across this resistor is referenced to the input common, so the output voltage is also referred to that node.

To provide rejection of this common voltage, an auxiliary amplifier (not shown) is included, which senses the voltage difference between input and output commons and cancels this error component. Thus, for zero differential signal input between A1HI and A1LO, the output A1OP simply follows the voltage at A1CM. Note that the range of voltage differences which can exist between A1LO and A1CM (or A2LO and A2CM) is limited to about ±100 mV. Figure 50 (one of the typical performance curves at the end of this data sheet) shows typical common-mode rejection ratio versus frequency.

ACHIEVING 80 dB GAIN RANGE

The two amplifier sections of the X-AMP can be connected in series to achieve higher gain. In this mode, the output of A1 (A1OP and A1CM) drives the input of A2 via a high-pass network (usually just a capacitor) that rejects the dc offset. The nominal gain range is now −2 dB to +82 dB for the AD600 or −22 dB to +62 dB for the AD602.

There are several options in connecting the gain-control inputs. The choice depends on the desired signal-to-noise ratio (SNR) and gain error (output ripple). The following examples feature the AD600; the arguments generally apply to the AD602, with appropriate changes to the gain values.

Sequential Mode (Maximum S/N Ratio)

In the sequential mode of operation, the SNR is maintained at its highest level for as much of the gain control range possible, as shown in Figure 2. Note here that the gain range is 0 dB to 80 dB. Figure 3 shows the general connections to accomplish this. Both gain-control inputs, C1HI and C2HI, are driven in parallel by a positive only, ground referenced source with a range of 0 V to +2.5 V.

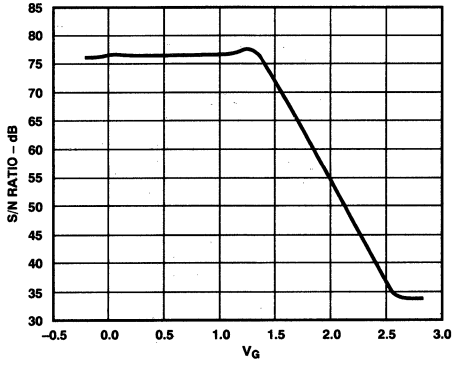

Figure 2. S/N Ratio vs. Control Voltage Sequential Control (1 MHz Bandwidth)

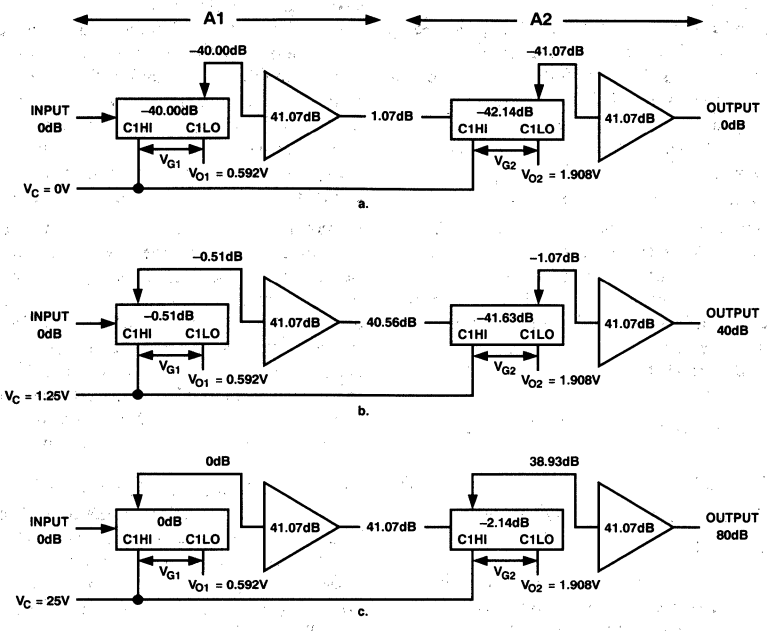

Figure 3. AD600 Gain Control Input Calculations for Sequential Control Operation

The gains are offset (Figure 4) such that A2's gain is increased only after A1's gain has reached its maximum value. Note that for a differential input of −700 mV or less, the gain of a single amplifier (A1 or A2) will be at its minimum value of −1.07 dB; for a differential input of +700 mV or more, the gain will be at its maximum value of 41.07 dB. Control inputs beyond these limits will not affect the gain and can be tolerated without damage or foldover in the response. See the Specifications Section of this data sheet for more details on the allowable voltage range. The gain is now

$$Gain\ (dB) = 32\ V_C \qquad (3)$$

where V_C is the applied control voltage.

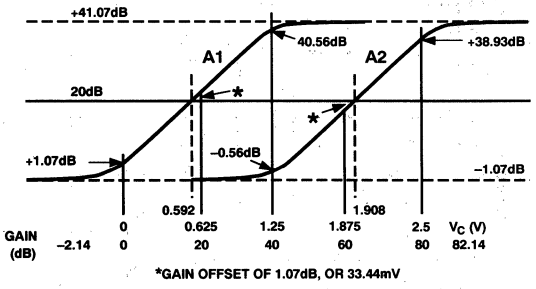

Figure 4. Explanation of Offset Calibration for Sequential Control

When V_C is set to zero, V_{G1} = −0.592 V and the gain of A1 is +1.07 dB (recall that the gain of each amplifier section is 0 dB for V_G = −625 mV); meanwhile, V_{G2} = −1.908 V so the gain of A2 is −1.07 dB. The overall gain is thus 0 dB (see Figure 3a). When V_C = +1.25 V, V_{G1} = 1.25 V − 0.592 V = +0.658 V, which sets the gain of A1 to 40.56 dB, while V_{G2} = 1.25 V − 1.908 V = −0.658 V, which sets A2's gain at −0.56 dB. The overall gain is now 40 dB (see Figure 3b). When V_C = +2.5 V, the gain of A1 is 41.07 dB and that of A2 is 38.93 dB, resulting in an overall gain of 80 dB (see Figure 3c). This mode of operation is further clarified by Figure 5, which is a plot of the separate gains of A1 and A2 and the overall gain versus the control voltage. Figure 6 is a plot of the gain error of the cascaded amplifiers versus the control voltage.

Parallel Mode (Simplest Gain-Control Interface)

In this mode, the gain-control voltage is applied to both inputs in parallel — C1HI and C2HI are connected to the control voltage, and C1LO and C2LO are optionally connected to an offset voltage of +0.625 V. The gain scaling is then doubled to 64 dB/V, requiring only 1.25 V for an 80 dB change of gain. The amplitude of the gain ripple in this case is also doubled, as shown in Figure 7, and the instantaneous signal-to-noise ratio at the output of A2 decreases linearly as the gain is increased (Figure 8).

Low Ripple Mode (Minimum Gain Error)

As can be seen in Figures 6 and 7, the output ripple is periodic. By offsetting the gains of A1 and A2 by half the period of the ripple, or 3 dB, the residual gain errors of the two amplifiers can be made to cancel. Figure 9 shows the much lower gain ripple when configured in this manner. Figure 10 plots the S/N ratio as a function of gain; it is very similar to that in the "Parallel Mode."

APPLICATIONS

The full potential of any high performance amplifier can only be realized by careful attention to details in its applications. The following pages describe fully tested circuits in which many such details have already been considered. However, as is always true of high accuracy, high speed analog circuits, the schematic is only part of the story; this is no less true for the AD600 and AD602. Appropriate choices in the overall board layout and the type and placement of power supply decoupling components are very important. As explained previously, the input grounds A1LO and A2LO must use the shortest possible connections.

The following circuits show examples of time-gain control for ultrasound and for sonar, methods for increasing the output drive, and AGC amplifiers for audio and RF/IF signal processing using both peak and rms detectors. These circuits also illustrate methods of cascading X-AMPs for either maintaining the optimal S/N ratio or maximizing the accuracy of the gain-control voltage for use in signal measurement. These AGC circuits may be modified for use as voltage-controlled amplifiers for use in sonar and ultrasound applications by removing the detector and substituting a DAC or other voltage source for supplying the control voltage.

Time-Gain Control (TGC) and Time-Variable Gain (TVG)

Ultrasound and sonar systems share a similar requirement: both need to provide an exponential increase in gain in response to a linear control voltage, that is, a gain control that is "linear in dB." Figure 11 shows the AD600/AD602 configured for a control voltage ramp starting at −625 mV and ending at +625 mV for a gain-control range of 40 dB. For simplicity, only the A1 connections are shown. The polarity of the gain-control voltage may be reversed and the control voltage inputs C1HI and C1LO reversed to achieve the same effect. The gain-control voltage can be supplied by a voltage-output DAC such as the AD7242, which contains two complete DACs, operates from ±5 V supplies, has an internal reference of 3 V, and provides ±3 V of output swing. As such it is well-suited for use with the AD600/AD602, needing only a few resistors to scale the output voltage of the DACs to the levels needed by the AD600/AD602.

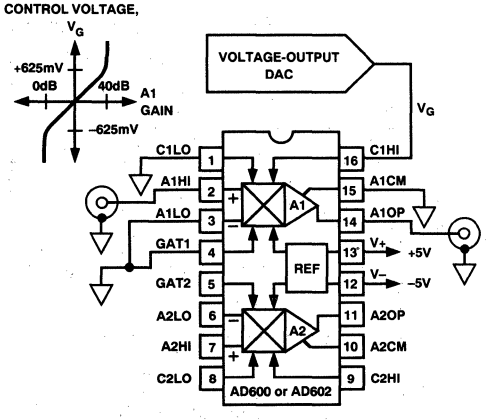

Figure 11. The Simplest Application of the X-AMP is as a TGC or TVG Amplifier in Ultrasound or Sonar. Only the A1 Connections Are Shown for Simplicity.

Increasing Output Drive

The AD600/AD602's output stage has limited capability for negative-load driving capability. For driving loads less than 500 Ω, the load drive may be increased by about 5 mA by connecting a 1 kΩ pull-down resistor from the output to the negative supply (Figure 12).

Driving Capacitive Loads

For driving capacitive loads of greater than 5 pF, insert a 10 Ω resistor between the output and the load. This lowers the possibility of oscillation.

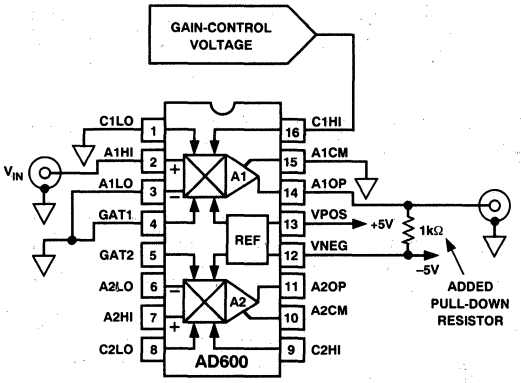

Figure 12. Adding a 1 kΩ Pull-Down Resistor Increases the X-AMP's Output Drive by About 5 mA. Only the A1 Connections Are Shown for Simplicity.

Realizing Other Gain Ranges

Larger gain ranges can be accommodated by cascading amplifiers. Combinations built by cascading two amplifiers include −20 dB to +60 dB (using one AD602), −10 dB to +70 dB (1/2 of an AD602 followed by 1/2 of an AD600), and 0 dB to 80 dB (one AD600). In multiple-channel applications, extra protection against oscillations can be provided by using amplifier sections from different packages.

An Ultralow Noise VCA

The two channels of the AD600 or AD602 may be operated in parallel to achieve a 3 dB improvement in noise level, providing 1 nV/$\sqrt{\text{Hz}}$ without any loss of gain accuracy or bandwidth.

In the simplest case, as shown in Figure 13, the signal inputs A1HI and A2HI are tied directly together, the outputs A1OP and A2OP are summed via R1 and R2 (100 Ω each), and the control inputs C1HI/C2HI and C1LO/C2LO operate in parallel. Using these connections, both the input and output resistances are 50 Ω. Thus, when driven from a 50 Ω source and terminated in a 50 Ω load, the gain is reduced by 12 dB, so the gain range becomes −12 dB to +28 dB for the AD600 and −22 dB to +18 dB for the AD602. The peak input capability remains unaffected (1 V rms at the IC pins, or 2 V rms from an unloaded 50 Ω source). The loading on each output, with a 50 Ω load, is effectively 200 Ω, because the load current is shared between the two channels, so the overall amplifier still meets its specified maximum output and distortion levels for a 200 Ω load. This amplifier can deliver a maximum sine wave power of +10 dBm to the load.

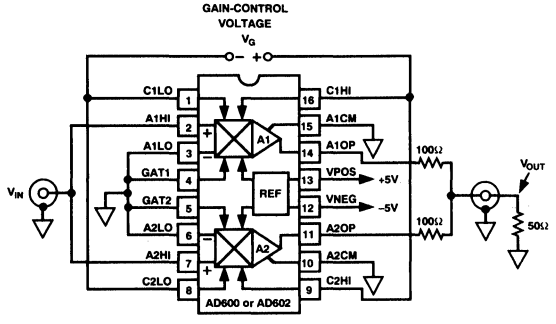

Figure 13. An Ultralow Noise VCA Using the AD600 or AD602

A Low Noise, 6 dB Preamplifier

In some ultrasound applications, the user may wish to use a high input impedance preamplifier to avoid the signal attenuation that would result from loading the transducer by the 100 Ω input resistance of the X-AMP. High gain cannot be tolerated, because the peak transducer signal is typically ±0.5 V, while the peak input capability of the AD600 or AD602 is only slightly more than ±1 V. A gain of two is a suitable choice. It can be shown that if the preamplifier's overall referred-to-input (RTI) noise is to be the same as that due to the X-AMP alone (1.4 nV/$\sqrt{\text{Hz}}$), then the input noise of a X2 preamplifier must be $\sqrt{(3/4)}$ times as large, that is, 1.2 nV/$\sqrt{\text{Hz}}$.

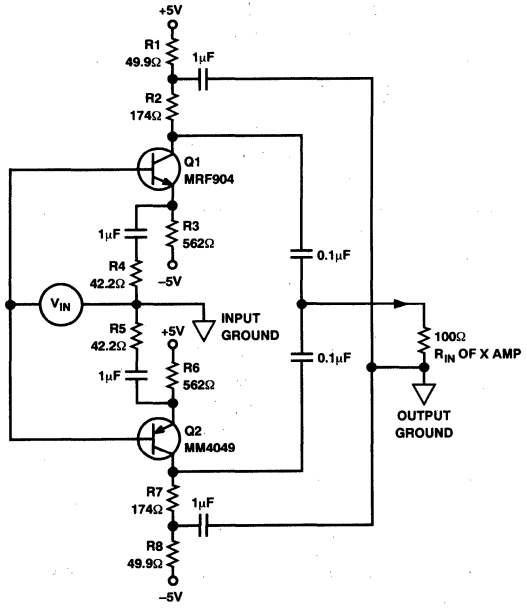

Figure 14. A Low Noise Preamplifier for the AD600 and AD602

An inexpensive circuit, using complementary transistor types chosen for their low $r_{bb'}$, is shown in Figure 14. The gain is determined by the ratio of the net collector load resistance to the net emitter resistance, that is, it is an open-loop amplifier. The gain will be X2 (6 dB) only into a 100 Ω load, assumed to be provided by the input resistance of the X-AMP; R2 and R7 are in shunt with this load, and their value is important in defining the gain. For small-signal inputs, both transistors contribute an equal transconductance, which is rendered less sensitive to signal level by the emitter resistors R4 and R5, which also play a dominant role in setting the gain.

This is a Class AB amplifier. As V_{IN} increases in a positive direction, Q1 conducts more heavily and its r_e becomes lower while that of Q2 increases. Conversely, more negative values of V_{IN} result in the r_e of Q2 decreasing, while that of Q1 increases. The design is chosen such that the net emitter resistance is essentially independent of the instantaneous value of V_{IN}, resulting in moderately low distortion. Low values of resistance and moderately high bias currents are important in achieving the low noise, wide bandwidth, and low distortion of this preamplifier. Heavy decoupling prevents noise on the power supply lines from being conveyed to the input of the X-AMP.

Table I. Measured Preamplifier Performance

Measurement		Value	Units
Gain (f = 30 MHz)		6	dB
Bandwidth (−3 dB)		250	MHz
Input Signal for			
1 dB Compression		1	V p-p

Quiescent Current		15	mA

A Low Noise AGC Amplifier with 80 dB Gain Range

Figure 15 provides an example of the ease with which the AD600 can be connected as an AGC amplifier. A1 and A2 are cascaded, with 6 dB of attenuation introduced by the 100 Ω resistor R1, while a time constant of 5 ns is formed by C1 and the 50 Ω of net resistance at the input of A2. This has the dual effect of (a) lowering the overall gain range from {0 dB to 80 dB} to {6 dB to 74 dB} and (b) introducing a single-pole low-pass filter with a −3 dB frequency of about 32 MHz. This ensures stability at the maximum gain for a slight reduction in the overall bandwidth. The capacitor C4 blocks the small dc offset voltage at the output of A1 (which might otherwise saturate A2 at its maximum gain) and introduces a high pass corner at about 8 kHz, useful in eliminating low frequency noise and spurious signals which may be present at the input.

20

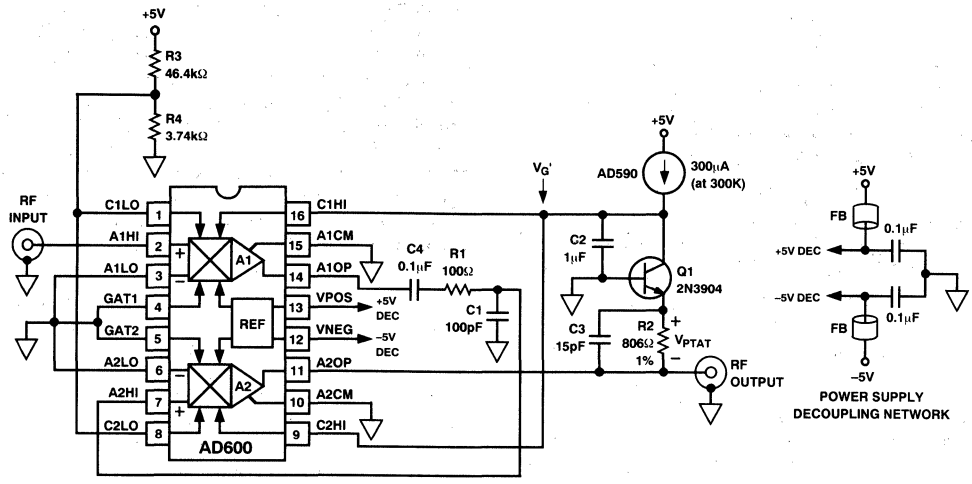

Figure 15. This Accurate HF AGC Amplifier Uses Just Three Active Components.

A simple half-wave detector is used, based on Q1 and R2. The average current into capacitor C2 is just the difference between the current provided by the AD590 (300 μA at 300 K, 27°C) and the collector current of Q1. In turn, the control voltage V_G is the time integral of this *error* current. When V_G (and thus the gain) is stable, the rectified current in Q1 must, on average, exactly balance the current in the AD590. If the output of A2 is too small to do this, V_G will ramp up, causing the gain to increase, until Q1 conducts sufficiently. The operation of this control system will now be described in detail.

First, consider the particular case where R2 *is zero* and the output voltage V_{OUT} is a square wave at, say, 100 kHz, that is, well above the corner frequency of the control loop. During the time V_{OUT} is negative, Q1 conducts; when V_{OUT} is positive, it is cut off. Since the *average* collector current is forced to be 300 μA, and the square wave has a 50% duty-cycle, the current when conducting must be 600 μA. With R2 omitted, the peak value of V_{OUT} would be just the V_{BE} of Q1 at 600 μA (typically about 700 mV) or 2 V_{BE} peak-to-peak. This voltage, hence the amplitude at which the output stabilizes, has a strong negative temperature coefficient (TC), typically −1.7 mV/°C. While this may not be troublesome in some applications, the correct value of R2 will render the output stable with temperature.

To understand this, first note that the current in the AD590 is closely proportional to absolute temperature (PTAT). (In fact, this IC is intended for use as a thermometer.) For the moment, continue to assume that the signal is a square wave. When Q1 is conducting, V_{OUT} is the now the *sum* of V_{BE} and a voltage which is PTAT and which can be chosen to have an equal but opposite TC to that of the base-to-emitter voltage. This is actually nothing more than the "bandgap voltage reference" principle in thinly veiled disguise! When we choose R2 such that the sum of the voltage across it and the V_{BE} of Q1 is close to the bandgap voltage of about 1.2 V, V_{OUT} will be stable over a wide range of temperatures, provided, of course, that Q1 and the AD590 share the same thermal environment.

Since the average emitter current is 600 μA during each half-cycle of the square wave, a resistor of 833 Ω would add a PTAT voltage of 500 mV at 300 K, increasing by 1.66 mV/°C. In practice, the optimum value of R2 will depend on the transistor used, and, to a lesser extent, on the waveform for which the temperature stability is to be optimized; for the devices shown and sine wave signals, the recommended value is 806 Ω. This resistor also serves to lower the peak current in Q1 and the 200 Hz LP filter it forms with C2 helps to minimize distortion due to ripple in V_G. Note that the output amplitude under sine wave conditions will be higher than for a square wave, since the average value of the current *for an ideal rectifier* would be 0.637 times as large, causing the output amplitude to be 1.88 (=1.2/0.637) V, or 1.33 V rms. In practice, the somewhat non-ideal rectifier results in the sine wave output being regulated to about 1.275 V rms.

An offset of +375 mV is applied to the inverting gain-control inputs C1LO and C2LO. Thus the nominal −625 mV to +625 mV range for V_G is translated upwards (at V_G') to −0.25 V for minimum gain to +1 V for maximum gain. This prevents Q1 from going into heavy saturation at low gains and leaves sufficient "headroom" of 4 V for the AD590 to operate correctly at high gains when using a +5 V supply.

In fact, the 6 dB interstage attenuator means that the overall gain of this AGC system actually runs from −6 dB to +74 dB. Thus, an input of 2 V rms would be required to produce a 1 V rms output at the minimum gain, which exceeds the 1 V rms maximum input specification of the AD600. The *available gain* range is therefore 0 dB to 74 dB (or, X1 to X5000). Since the gain scaling is 15.625 mV/dB (because of the cascaded stages) the minimum value of V_G' is actually increased by 6 × 15.625 mV, or about 94 mV, to −156 mV, so the risk of saturation in Q1 is reduced.

The emitter circuit of Q1 is somewhat inductive (due its finite f_t and base resistance). Consequently, the effective value of R2 increases with frequency. This would result in an increase in the stabilized output amplitude at high frequencies, but for the

addition of C3, determined experimentally to be 15 pF for the 2N3904 for maximum response flatness. Alternatively, a faster transistor can be used here to reduce HF peaking. Figure 16 shows the ac response at the stabilized output level of about 1.3 V rms. Figure 17 demonstrates the output stabilization for sine wave inputs of 1 mV to 1 V rms at frequencies of 100 kHz, 1 MHz and 10 MHz.

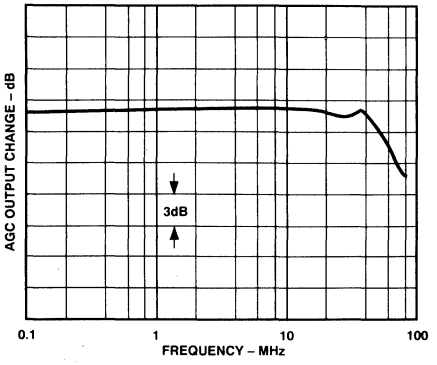

Figure 16. AC Response at the Stabilized Output Level of 1.3 V RMS

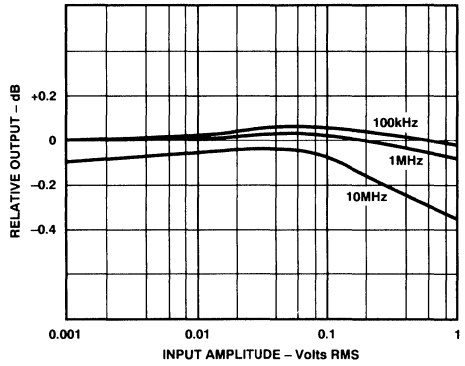

Figure 17. Output Stabilization vs. RMS Input for Sine Wave Inputs at 100 kHz, 1 MHz, and 10 MHz

While the "bandgap" principle used here sets the output amplitude to 1.2 V (for the square wave case), the stabilization point can be set to any higher amplitude, up to the maximum output of $\pm$ (V_S – 2) V which the AD600 can support. It is only necessary to split R2 into two components of appropriate ratio whose parallel sum remains close to the zero-TC value of 806 Ω. This is illustrated in Figure 18, which shows how the output can be raised, without altering the temperature stability.

Low Noise, 90 MHz Variable-Gain Amplifier

AD603*

FEATURES
"Linear in dB" Gain Control
Pin Programmable Gain Ranges
−11 dB to +31 dB with 90 MHz Bandwidth
+9 dB to +51 dB with 9 MHz Bandwidth
Any Intermediate Range, e.g., −1 dB to +41 dB with 45 MHz Bandwidth
Bandwidth Independent of Variable Gain
1.3 nV/$\sqrt{Hz}$ Input Noise Spectral Density
±0.5 dB Typical Gain Accuracy
MIL-STD-883 Compliant and DESC Versions Available

APPLICATIONS
RF/IF AGC Amplifier
Video Gain Control
A/D Range Extension
Signal Measurement

PRODUCT DESCRIPTION

The AD603 is a low noise, voltage-controlled amplifier for use in RF and IF AGC systems. It provides accurate, pin selectable gains of −11 dB to +31 dB with a bandwidth of 90 MHz or +9 dB to +51 dB with a bandwidth of 9 MHz. Any intermediate gain range may be arranged using one external resistor. The input referred noise spectral density is only 1.3 nV/$\sqrt{Hz}$ and power consumption is 125 mW at the recommended ±5 V supplies.

The decibel gain is "linear in dB," accurately calibrated, and stable over temperature and supply. The gain is controlled at a high impedance (50 MΩ), low bias (200 nA) differential input; the scaling is 25 mV/dB, requiring a gain-control voltage of only 1 V to span the central 40 dB of the gain range. An over- and under-range of 1 dB is provided whatever the selected range. The gain-control response time is less than 1 μs for a 40 dB change.

The differential gain-control interface allows the use of either differential or single-ended positive or negative control voltages. Several of these amplifiers may be cascaded and their gain-control gains offset to optimize the system S/N ratio.

The AD603 can drive a load impedance as low as 100 Ω with low distortion. For a 500 Ω load in shunt with 5 pF, the total harmonic distortion for a ±1 V sinusoidal output at 10 MHz is typically −60 dBc. The peak specified output is ±2.5 V minimum into a 500 Ω load, or ±1 V into a 100 Ω load.

The AD603 uses a proprietary circuit topology—the X-AMP™. The X-AMP comprises a variable attenuator of 0 dB to −42.14 dB followed by a fixed-gain amplifier. Because of the attenuator, the amplifier never has to cope with large inputs and can use negative feedback to define its (fixed) gain and dynamic performance. The attenuator has an input resistance of 100 Ω, laser trimmed to ±3%, and comprises a seven-stage R-2R ladder network, resulting in an attenuation between tap points of 6.021 dB. A proprietary interpolation technique provides a continuous gain-control function which is linear in dB.

The AD603A is specified for operation from −40°C to +85°C and is available in both 8-pin SOIC (R) and 8-pin ceramic DIP (Q). The AD603S is specified for operation from −55°C to +125°C and is available in an 8-pin ceramic DIP (Q). The AD603 is also available under DESC SMD 5962-94572.

*Patented.
X-AMP is a trademark of Analog Devices, Inc.

NOTES

[1]Typical open or short-circuited input; noise is lower when system is set to maximum gain and input is short-circuited. This figure includes the effects of both voltage and current noise sources.

[2]Using resistive loads of 500 Ω or greater, or with the addition of a 1 kΩ pull-down resistor when driving lower loads.

[3]The dc gain of the main amplifier in the AD603 is ×35.7; thus, an input offset of 100 μV becomes a 3.57 mV output offset.

Specifications shown in **boldface** are tested on all production units at final electrical test. Results from those tests are used to calculate outgoing quality levels. All min and max specifications are guaranteed, although only those shown in **boldface** are tested on all production units.

Specifications subject to change without notice.

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the AD603 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

THEORY OF OPERATION

The AD603 comprises a fixed-gain amplifier, preceded by a broadband passive attenuator of 0 to 42.14 dB, having a gain-control scaling factor of 40 dB per volt. The fixed gain is laser-trimmed in two ranges, to either 31.07 dB (×35.8) or 50 dB (×358), or may be set to any range in between using one external resistor between Pins 5 and 7. Somewhat higher gain can be obtained by connecting the resistor from Pin 5 to common, but the increase in output offset voltage limits the maximum gain to about 60 dB. For any given range, the bandwidth is independent of the voltage-controlled gain. This system provides an under- an over-range of 1.07 dB in all cases; for example, the overall gain is -11.07 dB to 31.07 dB in the maximum-bandwidth mode (Pin 5 and Pin 7 strapped).

This *X-AMP* structure has many advantages over former methods of gain-control based on nonlinear elements. Most importantly, the fixed-gain amplifier can use negative feedback to increase its accuracy. Since large inputs are first attenuated, the amplifier input is always small. For example, to deliver a ± 1 V output in the -1 dB/+41 dB mode (that is, using a fixed amplifier gain of 41.07 dB) its input is only 8.84 mV; thus the distortion can be very low. Equally important, the small-signal gain and phase response, and thus the pulse response, are essentially independent of gain.

Figure 1 is a simplified schematic. The input attenuator is a seven-section R-2R ladder network, using untrimmed resistors of nominally R= 62.5 Ω, which results in a characteristic resistance of 125 Ω ± 20%. A shunt resistor is included at the input and laser trimmed to establish a more exact input resistance of 100 Ω ± 3%, which ensures accurate operation (gain and HP corner frequency) when used in conjunction with external resistors or capacitors.

The nominal maximum signal at input VINP is 1 V rms (± 1.4 V peak) when using the recommended ± 5 V supplies, although operation to ± 2 V peak is permissible with some increase in HF distortion and feedthrough. *Pin 4 (SIGNAL COMMON) must be connected directly to the input ground; significant impedance in this connection will reduce the gain accuracy.*

The signal applied at the input of the ladder network is attenuated by 6.02 dB by each section; thus, the attenuation to each of the taps is progressively 0 dB, 6.02 dB, 12.04 dB, 18.06 dB, 24.08 dB, 30.1 dB, 36.12 dB and 42.14 dB. A unique circuit technique is employed to interpolate between these tap-points, indicated by the "slider" in Figure 1, thus providing continuous attenuation from 0 dB to 42.14 dB. It will help, in understanding the AD603, to think in terms of a mechanical means for moving this slider from left to right; in fact, its "position" is controlled by the voltage between Pins 1 and 2. The details of the gain-control interface are discussed later.

The gain is at all times very exactly determined, and a linear-in-dB relationship is automatically guaranteed by the exponential nature of the attenuation in the ladder network (the X-AMP principle). In practice, the gain deviates slightly from the ideal law, by about ± 0.2 dB peak (see, for example, Figure 16).

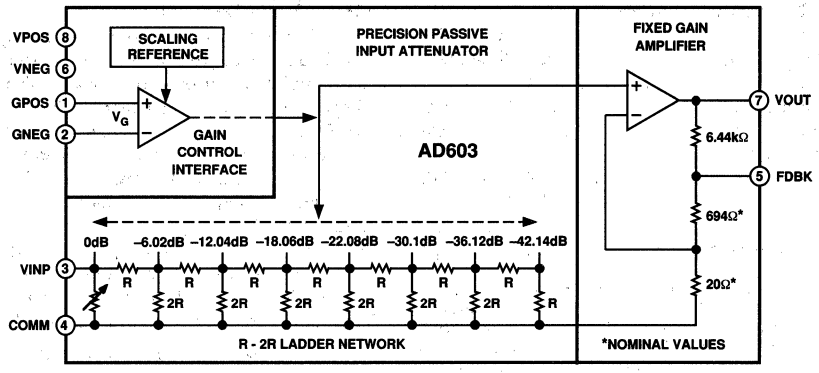

Figure 1. Simplified Block Diagram of the AD603

Noise Performance

An important advantage of the X-AMP is its superior noise performance. The nominal resistance seen at inner tap points is 41.7 Ω (one third of 125 Ω), which exhibits a Johnson noise-spectral density (NSD) of 0.83 nV/$\sqrt{\text{Hz}}$ (that is, $\sqrt{4kTR}$) at 27°C, which is a large fraction of the total input noise. The first stage of the amplifier contributes a further 1 nV/$\sqrt{\text{Hz}}$, for a total input noise of 1.3 nV/$\sqrt{\text{Hz}}$. It will be apparent that it is essential to use a low resistance in the ladder network to achieve the very low specified noise level. The signal's source impedance forms a voltage divider with the AD603's 100 Ω input resistance. In some applications, the resulting attenuation may be unacceptable, requiring the use of an external buffer or preamplifier to match a high impedance source to the low impedance AD603.

The noise at maximum gain (that is, at the 0 dB tap) depends on whether the input is short-circuited or open-circuited: when shorted, the minimum NSD of slightly over 1 nV/$\sqrt{\text{Hz}}$ is achieved; when open, the resistance of 100 Ω looking into the first tap generates 1.29 nV/$\sqrt{\text{Hz}}$, so the noise increases to a total of 1.63 nV/$\sqrt{\text{Hz}}$. (This last calculation would be important if the AD603 were preceded by, for example, a 900 Ω resistor to allow operation from inputs up to 10 V rms.) As the selected tap moves away from the input, the dependence of the noise on source impedance quickly diminishes.

Apart from the small variations just discussed, the signal-to-noise (S/N) ratio at the output is essentially independent of the attenuator setting. For example, on the −11 dB/+31 dB range the fixed gain of X35.8 raises the output NSD to 46.5 nV/$\sqrt{\text{Hz}}$. Thus, for the maximum undistorted output of 1 V rms and a 1 MHz bandwidth, the output S/N ratio would be 86.6 dB, that is, 20 log (1 V/46.5 μV).

The Gain-Control Interface

The attenuation is controlled through a differential, high-impedance (50 MΩ) input, with a scaling factor which is laser-trimmed to 40 dB per volt, that is, 25 mV/dB. An internal bandgap reference ensures stability of the scaling with respect to supply and temperature variations.

When the differential input voltage V_G = 0 V, the attenuator "slider" is centered, providing an attenuation of 21.07 dB. For the maximum bandwidth range, this results in an overall gain of 10 dB (= −21.07 dB + 31.07 dB). When the control input is −500 mV, the gain is lowered by 20 dB (= 0.500 V × 40 dB/V), to −10 dB; when set to +500 mV, the gain is increased by 20 dB, to 30 dB. When this interface is overdriven in either direction, the gain approaches either −11.07 dB (= −42.14 dB + 31.07 dB) or 31.07 dB (= 0 + 31.07 dB), respectively. The only constraint on the gain-control voltage is that it be kept within the common-mode range (−1.2 V to +2.0 V assuming +5 V supplies) of the gain control interface.

The basic gain of the AD603 can thus be calculated using the following simple expression:

$$Gain\ (dB) = 40\ V_G + 10 \qquad \text{Eq. (1)}$$

where V_G is in volts. When Pins 5 and 7 are strapped (see next section) the gain becomes

$$Gain\ (dB) = 40\ V_G + 20\ for\ 0\ to\ +40\ dB$$

and

$$Gain\ (dB) = 40\ V_G + 30\ for\ +10\ to\ +50\ dB \qquad \text{Eq. (2)}$$

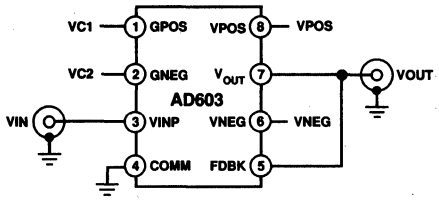
The high impedance gain-control input ensures minimal loading when driving many amplifiers in multiple channel or cascaded applications. The differential capability provides flexibility in choosing the appropriate signal levels and polarities for various control schemes.

For example, if the gain is to be controlled by a DAC providing a positive only ground-referenced output, the "Gain Control LO" (GNEG) pin should be biased to a fixed offset of +500 mV, to set the gain to −10 dB when "Gain Control HI" (GPOS) is at zero, and to 30 dB when at +1.00 V.

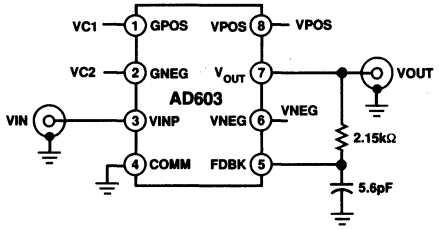
It is a simple matter to include a voltage divider to achieve other scaling factors. When using an 8-bit DAC having a FS output of +2.55 V (10 mV/bit), a divider ratio of 2 (generating 5 mV/bit) would result in a gain-setting resolution of 0.2 dB/bit. The use of such offsets is valuable when two AD603s are cascaded, when various options exist for optimizing the S/N profile, as will be shown later.

Programming the Fixed-Gain Amplifier Using Pin Strapping

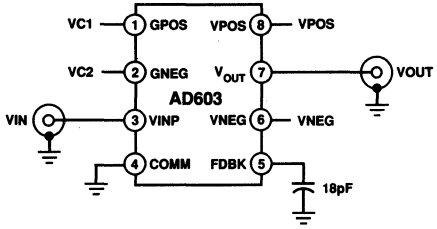
Access to the feedback network is provided at Pin 5 (FDBK). The user may program the gain of the AD603's output amplifier using this pin, as shown in Figure 2. There are three modes: in the default mode, FDBK is unconnected, providing the range +9 dB/+51 dB; when V_{OUT} and FDBK are shorted, the gain is lowered to −11 dB/+31 dB; when an external resistor is placed between V_{OUT} and FDBK any intermediate gain can be achieved, for example, −1 dB/+41 dB. Figure 3 shows the nominal maximum gain versus external resistor for this mode.



a. −10 dB to +30 dB; 90 MHz Bandwidth



b. 0 dB to 40 dB; 45 MHz Bandwidth



c. +10 dB to 50 dB; 9 MHz Bandwidth

Figure 2. Pin Strapping to Set Gain

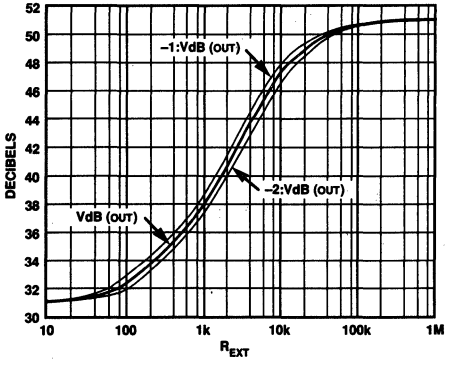


Figure 3. Gain vs. R_{EXT}, Showing Worst-Case Limits Assuming Internal Resistors Have a Maximum Tolerance of 20%

Optionally, when a resistor is placed from FDBK to COMM, higher gains can be achieved. This fourth mode is of limited value because of the low bandwidth and the elevated output offsets; it is thus not included in Figure 2.

The gain of this amplifier in the first two modes is set by the ratio of on-chip laser-trimmed resistors. While the ratio of these resistors is very accurate, the absolute value of these resistors can vary by as much as ±20%. Thus, when an external resistor is connected in parallel with the nominal 6.44 kΩ ± 20% internal resistor, the overall gain accuracy is somewhat poorer. The worst-case error occurs at about 2 kΩ (see Figure 4).

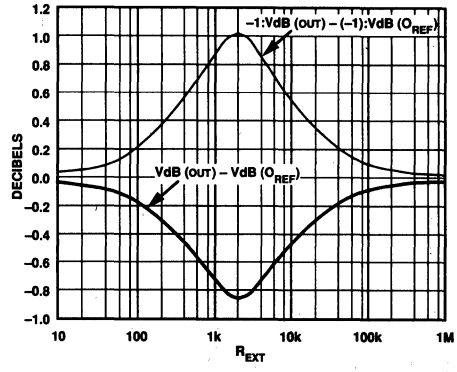

Figure 4. Worst-Case Gain Error, Assuming Internal Resistors Have a Maximum Tolerance of −20% (Top Curve) or +20% (Bottom Curve)

While the gain-bandwidth product of the fixed-gain amplifier is about 4 GHz, the actual bandwidth is not exactly related to the maximum gain. This is because there is a slight enhancing of the ac response magnitude on the maximum bandwidth range, due to higher order poles in the open-loop gain function; this mild peaking is not present on the higher gain ranges. Figure 2 shows how optional capacitors may be added to extend the frequency response in high gain modes.

CASCADING TWO AD603s

Two or more AD603s can be connected in series to achieve higher gain. Invariably, ac coupling must be used to prevent the dc offset voltage at the output of each amplifier from overloading the following amplifier at maximum gain. The required high pass coupling network will usually be just a capacitor, chosen to set the desired corner frequency in conjunction with the well-defined 100 Ω input resistance of the following amplifier.

For two AD603s, the total gain-control range becomes 84 dB (two times 42.14 dB); the overall −3 dB bandwidth of cascaded stages will be somewhat reduced. Depending on the pin-strapping, the gain and bandwidth for two cascaded amplifiers can range from −22 dB to +62 dB (with a bandwidth of about 70 MHz) to +22 dB to +102 dB (with a bandwidth of about 6 MHz).

There are several ways of connecting the gain-control inputs in cascaded operation. The choice depends on whether it is important to achieve the highest possible Instantaneous Signal-to-Noise Ratio (ISNR), or, alternatively, to minimize the ripple in the gain error. The following examples feature the AD603 programmed for maximum bandwidth; the explanations apply to other gain/bandwidth combinations with appropriate changes to the arrangements for setting the maximum gain.

Sequential Mode (Optimal S/N Ratio)

In the sequential mode of operation, the ISNR is maintained at its highest level for as much of the gain control range possible. Figure 5, shows the SNR over a gain range of −22 dB to +62 dB, assuming an output of 1 V rms and a 1 MHz bandwidth; Figure 6 shows the general connections to accomplish this. Here, both the positive gain-control inputs (GPOS) are driven in parallel by a positive-only, ground-referenced source with a range of 0 V to +2 V, while the negative gain-control inputs (GNEG) are biased by stable voltages to provide the needed gain-offsets. These voltages may be provided by resistive dividers operating from a common voltage reference.

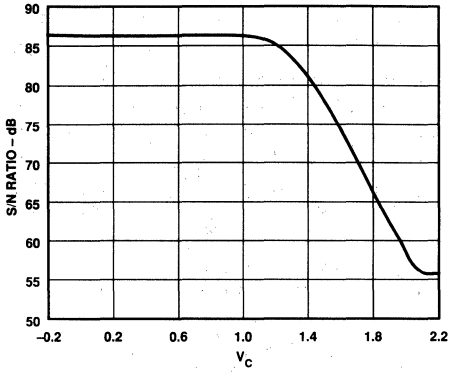

Figure 5. SNR vs. Control Voltage—Sequential Control (1 MHz) Bandwidth)

The gains are offset (Figure 7) such that A2's gain is increased only after A1's gain has reached its maximum value. Note that for a differential input of −600 mV or less, the gain of a single amplifier (A1 or A2) will be at its minimum value of −11.07 dB; for a differential input of +600 mV or more, the gain will be at its maximum value of 31.07 dB. Control inputs beyond these limits will not affect the gain and can be tolerated without damage or foldover in the response. This is an important aspect of the AD603's gain-control response. (See the Specifications section of this data sheet for more details on the allowable voltage range). The gain is now

$$Gain\ (dB) = 40V_G + G_O \qquad \text{Eq. (3)}$$

where V_G is the applied control voltage and G_O is determined by the gain range chosen. In the explanatory notes that follow, we assume the maximum-bandwidth connections are used, for which G_O is −20 dB.

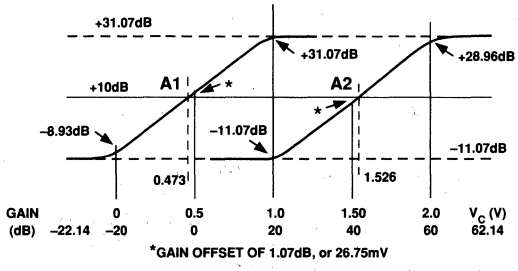

Figure 7. Explanation of Offset Calibration for Sequential Control

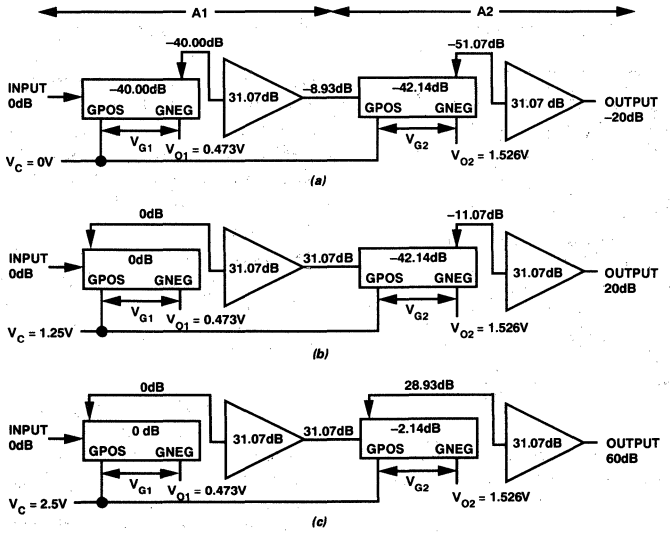

Figure 6. AD603 Gain Control Input Calculations for Sequential Control Operation

With reference to Figure 6, note that V_{G1} refers to the differential gain-control input to A1 and V_{G2} refers to the differential gain-control input to A2. When V_G is zero, $V_{G1} = -473$ mV and thus the gain of A1 is −8.93 dB (recall that the gain of each individual amplifier in the maximum-bandwidth mode is −10 dB for $V_G = -500$ mV and 10 dB for $V_G = 0$ V); meanwhile, VG2 = −1.908 V so the gain of A2 is "pinned" at −11.07 dB. The overall gain is thus −20 dB. This situation is shown in Figure 6a.

When $V_G = +1.00$ V, $V_{G1} = 1.00$ V − 0.473 V = +0.526 V, which sets the gain of A1 to at nearly its maximum value of 31.07 dB, while $V_{G2} = 1.00$ V − 1.526 V = −0.526 V, which sets A2's gain at nearly its minimum value −11.07 dB. Close analysis shows that the degree to which neither AD603 is completely pushed to its maximum or minimum gain exactly cancels in the overall gain, which is now +20 dB. This is depicted in Figure 6b.

When $V_G = +2.0$ V, the gain of A1 is pinned at 31.07 dB and that of A2 is near its maximum value of 28.93 dB, resulting in an overall gain of 60 dB (see Figure 6c). This mode of operation is further clarified by Figure 8, which is a plot of the separate gains of A1 and A2 and the overall gain versus the control voltage. Figure 9 is a plot of the gain error of the cascaded amplifiers versus the control voltage. Figure 10 is a plot of the gain error of the cascaded stages versus the control voltages.

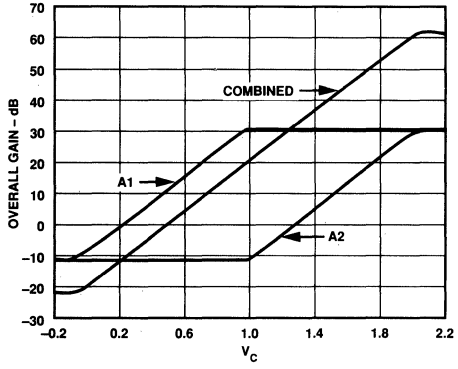

Figure 8. Plot of Separate and Overall Gains in Sequential Control

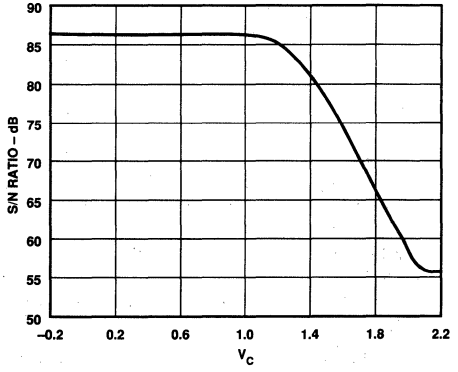

Figure 9. SNR for Cascaded Stages—Sequential Control

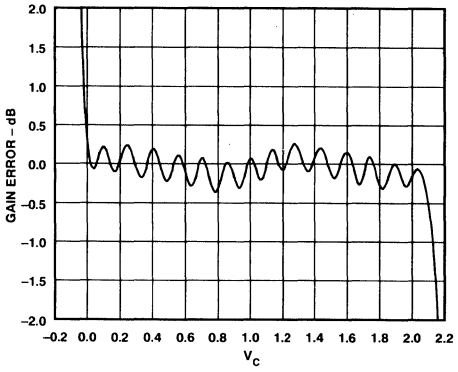

Figure 10. Gain Error for Cascaded Stages—Sequential Control

Parallel Mode (Simplest Gain-Control Interface)

In this mode, the gain-control of voltage is applied to both inputs in parallel—the GPOS pins of both A1 and A2 are connected to the control voltage and the GNEW inputs are grounded. The gain scaling is then doubled to 80dB/V, requiring only a 1.00 V change for an 80 dB change of gain:

$$Gain\ (dB) = 80\ V_G + G_O \qquad \text{Eq. (4)}$$

where, as before G_O depends on the range selected; for example, in the maximum-bandwidth mode, G_O is +20 dB. Alternatively, the GNEG pins may be connected to an offset voltage of +0.500 V, in which case, G_O is −20 dB.

The amplitude of the gain ripple in this case is also doubled, as shown in Figure 11, while the instantaneous signal-to-noise ratio at the output of A2 now decreases linearly as the gain increased (Figure 12).

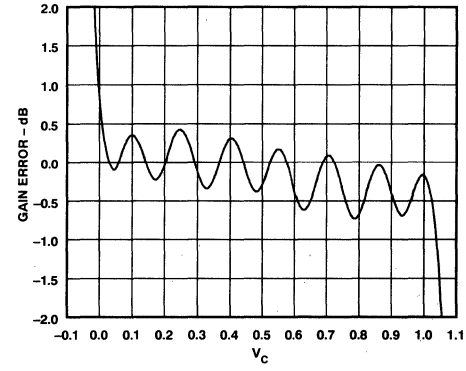

Figure 11. Gain Error for Cascaded Stages—Parallel Control

Low Gain Ripple Mode (Minimum Gain Error)

As can be seen from Figures 9 and 10, the error in the gain is periodic, that is, it shows a small ripple. (Note that there is also a variation in the *output offset voltage*, which is due to the gain

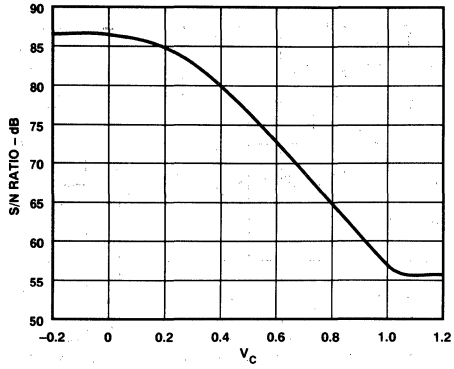

Figure 12. ISNR for Cascaded Stages—Parallel Control

interpolation, but this is not exact in amplitude.) By offsetting the gains of A1 and A2 by half the period of the ripple, that is, by 3 dB, the residual gain errors of the two amplifiers can be made to cancel. Figure 13 shows that much lower gain ripple when configured in this manner. Figure 14 plots the ISNR as a function of gain; it is very similar to that in the "Parallel Mode."

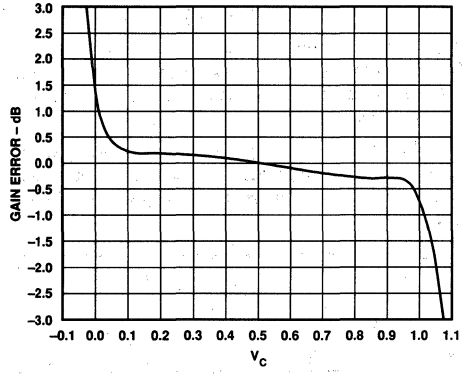

Figure 13. Gain Error for Cascaded Stages—Low Ripple Mode

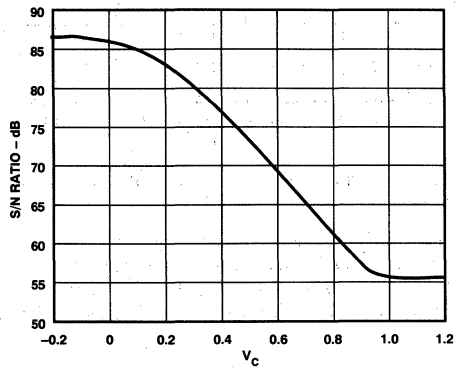

Figure 14. ISNR vs. Control Voltage—Low Ripple Mode

THEORY OF THE AD603

A Low Noise AGC Amplifier

Figure 15 shows the ease with which the AD603 can be connected as an AGC amplifier. The circuit illustrates many of the points previously discussed: It uses few parts, has linear-in-dB gain, operates from a single supply, uses two cascaded amplifiers in sequential gain mode for maximum S/N ratio, and an external resistor programs each amplifier's gain. It also uses a simple temperature-compensated detector.

The circuit operates from a single 10 V supply. Resistors R1, R2 and R3, R4 bias the common pins of A1 and A2 at 5 V. This pin is a low impedance point and must have a low impedance path to ground, here provided by the 100 μF tantalum capacitors and the 0.1 μF ceramic capacitors.

The cascaded amplifiers operate in sequential gain. Here, the offset voltage between the pins 2 (GNEG) of A1 and A2 is 1.05 V (42.14 dB × 25 mV/dB), provided by a voltage divider consisting of resistors R5, R6, and R7. Using standard values, the offset is not exact but it is not critical for this application.

The gain of both A1 and A2 is programmed by resistors R13 and R14, respectively, to be about 42 dB; thus the maximum gain of the circuit is twice that, or 84 dB. The gain-control range can be shifted up by as much as 20 dB by appropriate choices of R13 and R14.

The circuit operates as follows. A1 and A2 are cascaded. Capacitor C1 and the 100 Ω of resistance at the input of A1 form a time-constant of 10 μs. C2 blocks the small dc offset voltage at the output of A1 (which might otherwise saturate A2 at its maximum gain) and introduces a high-pass corner at about 16 kHz, eliminating low frequency noise.

A half-wave detector is used, based on Q1 and R8. The current into capacitor C_{AV} is just the difference between the collector current of Q2 (biased to be 300 μA at 300 K, 27°C) and the collector current of Q1, which increases with the amplitude of the output signal. The automatic gain control voltage, V_{AGC}, is the time-integral of this *error* current. In order for V_{AGC} (and thus the gain) to remain insensitive to short-term amplitude fluctuations in the output signal, the rectified current in Q1 must, on average, exactly balance the current in Q2. If the output of A2 is too small to do this, V_{AGC} will increase, causing the gain to increase, until Q1 conducts sufficiently.

Consider the case where R8 is zero and the output voltage V_{OUT} is a square wave at, say, 455 kHz, that is, well above the corner frequency of the control loop.

During the time V_{OUT} is negative with respect to the base voltage of Q1, Q1 conducts; when V_{OUT} is positive, it is cut off. Since the average collector current of Q1 is forced to be 300 μA, and the square wave has a duty-cycle of 1:1, Q1's collector current when conducting must be 600 μA. With R8 omitted, the peak amplitude of V_{OUT} is forced to be just the V_{BE} of Q1 at 600 μA, typically about 700 mV, or 2 V_{BE} peak-to-peak. This voltage, hence the amplitude at which the output stabilizes, has a strong negative temperature coefficient (TC), typically −1.7 mV/°C. Although this may not be troublesome in some applications, the correct value of R8 will render the output stable with temperature.

To understand this, first note that the current in Q2 is made to be proportional to absolute temperature (PTAT). For the moment, continue to assume that the signal is a square wave.

When Q1 is conducting, V_{OUT} is now the sum of V_{BE} and a voltage which is PTAT and which can be chosen to have an equal but opposite TC to that of the V_{BE}. This is actually nothing more than an application of the "bandgap voltage reference" principle. When R8 is chosen such that the sum of the voltage across it and the V_{BE} of Q1 is close to the bandgap voltage of about 1.2 V, V_{OUT} will be stable over a wide range of temperatures, provided, of course, that Q1 and Q2 share the same thermal environment.

Since the average emitter current is 600 μA during each half-cycle of the square wave a resistor of 833 Ω would add a PTAT voltage of 500 mV at 300 K, increasing by 1.66 mV/°C. In practice, the optimum value will depend on the type of transistor used, and, to a lesser extent, on the waveform for which the temperature stability is to be optimized; for the inexpensive 2N3904/2N306 pair and sine wave signals, the recommended value is 806 Ω.

This resistor also serves to lower the peak current in Q1 when more typical signals (usually, sinusoidal) are involved, and the 1.8 kHz LP filter it forms with C_{AV} helps to minimize distortion due to ripple in VAGC. Note that the output amplitude under sinewave conditions will be higher than for a square wave, since the average value of the current *for an ideal rectifier* would be 0.637 times as large, causing the output amplitude to be 1.88 (=1.2/0.637) V, or 1.33 V rms. In practice, the somewhat nonideal rectifier results in the sine wave output being regulated to about 1.4 V rms, or 3.6 V p-p.

The bandwidth of the circuit exceeds 40 MHz. At 10.7 MHz, the AGC threshold is 100 μV (−67 dBm) and its maximum gain is 83 dB (20 log 1.4V/100 μV). The circuit holds its output at 1.4 V rms for inputs as low as −67 dBm to +15 dBm (82 dB), where the input signal exceeds the AD603's maximum input rating. For a −30 dBm input at 10.7 MHz, the second harmonic is 34 dB down from the fundamental and the third harmonic is 35 dB down.

CAUTION

Careful component selection, circuit layout, power-supply decoupling, and shielding are needed to minimize the AD603's susceptibility to interference from radio and TV stations, etc. In bench evaluation, we recommend placing all of the components in a shielded box and using feedthrough decoupling networks for the supply voltage. Circuit layout and construction are also critical, since stray capacitances and lead inductances can form resonant circuits and are a potential source of circuit peaking, oscillation, or both.

50 MHz, 80 dB Demodulating Logarithmic Amplifier with Limiter Output

AD606

FEATURES

Logarithmic Amplifier Performance
- **−75 dBm to +5 dBm Dynamic Range**
- **≤1.5nV/√Hz Input Noise**
- **Usable to >50 MHz**
- **37.5 mV/dB Voltage Output**
- **On-Chip Low-Pass Output Filter**

Limiter Performance
- **±1 dB Output Flatness over 80 dB Range**
- **±3° Phase Stability at 10.7 MHz over 80 dB Range**
- **Adjustable Output Amplitude**

Low Power
- **+5 V Single Supply Operation**
- **65 mW Typical Power Consumption**
- **CMOS Compatible Power-Down to 325 μW typ**
- **<5 μs Enable/Disable Time**

APPLICATIONS

Ultrasound and Sonar Processing
Phase-Stable Limiting Amplifier to 100 MHz
Received Signal Strength Indicator (RSSI)
Wide Range Signal and Power Measurement

PRODUCT DESCRIPTION

The AD606 is a complete, monolithic logarithmic amplifier using a 9-stage "successive-detection" technique. It provides both logarithmic and limited outputs. The logarithmic output is from a three-pole post-demodulation low-pass filter and provides a loadable output voltage of +0.1 V dc to +4 V dc. The logarithmic scaling is such that the output is +0.5 V for a sinusoidal input of −75 dBm and +3.5 V at an input of +5 dBm; over this range the logarithmic linearity is typically within ±0.4 dB. All scaling parameters are proportional to the supply voltage.

The AD606 can operate above and below these limits, with reduced linearity, to provide as much as 90 dB of conversion range. A second low-pass filter automatically nulls the input offset of the first stage down to the submicrovolt level. Adding external capacitors to both filters allows operation at input frequencies as low as a few hertz.

The AD606's limiter output provides a hard-limited signal output as a differential current of ±1.2 mA from open-collector outputs. In a typical application, both of these outputs are loaded by 200 Ω resistors to provide a voltage gain of more than 90 dB from the input. Transition times are 1.5 ns, and the phase is stable to within ±3° at 10.7 MHz for signals from −75 dBm to +5 dBm.

The logarithmic amplifier operates from a single +5 V supply and typically consumes 65 mW. It is enabled by a CMOS logic-level voltage input, with a response time of <5 μs. When disabled, the standby power is reduced to <1 mW within 5 μs.

The AD606J is specified for the commercial temperature range of 0°C to +70°C and is available in 16-pin plastic DIPs or SOICs. Consult the factory for other packages and temperature ranges.

PIN FUNCTIONS

Pin	Mnemonic	Function
1	INLO	DIFFERENTIAL RF INPUT −75 dBm to +5 dBm, Inverting, AC Coupled.
2	COMM	POWER SUPPLY COMMON Connect to Ground.
3	ISUM	LOG DETECTOR SUMMING NODE
4	ILOG	LOG CURRENT OUTPUT Normally No Connection; 2 μA/dB Output Current.
5	BFIN	BUFFER INPUT Optionally Used to Realize Low Frequency Post-Demodulation Filters.
6	VLOG	BUFFERED LOG OUTPUT 37.5 mV/dB (100 mV to 4.5 V).
7	OPCM	OUTPUT COMMON Connect to Ground.
8	LMLO	DIFFERENTIAL LIMITER OUTPUT 1.2 mA Full-Scale Output Current. Open Collector Output Must Be "Pulled" Up to VPOS with R ≤ 400 Ω.
9	LMHI	DIFFERENTIAL LIMITER OUTPUT 1.2 mA Full-Scale Output Current. Open Collector Output Must Be "Pulled" Up to VPOS with R ≤ 400 Ω.
10	LADJ	LIMITER LEVEL ADJUSTMENT Optionally Used to Adjust Limiter Output Current.
11	FIL1	OFFSET LOOP LOW-PASS FILTER Normally No Connection; a Capacitor Between FIL1 and FIL2 May Be Added to Lower the Filter Cutoff Frequency.
12	FIL2	OFFSET LOOP LOW-PASS FILTER Normally No Connection; See Above.
13	VPOS	POSITIVE SUPPLY Connect to +5 V at 13 mA.
14	PRUP	POWER UP CMOS (5 V) Logical High = Device On (≈ 65 mW). CMOS (0 V) Logical Low = Device Off (≈ 325 μW).
15	COMM	POWER SUPPLY COMMON Connect to Ground.
16	INHI	DIFFERENTIAL RF INPUT −75 dBm to +5 dBm, Noninverting, AC Coupled.

INPUT LEVEL CONVENTIONS

RF logarithmic amplifiers usually have their input specified in "dBm," meaning "decibels with respect to 1 mW." Unfortunately, this is not precise for several reasons.

1. Log amps respond not to power but to voltage. In this respect, it would be less ambiguous to use "dBV" (decibels referred to 1 V) as the input metric. Also, power is dependent on the rms (root-mean-square) value of the signal, while log amps are not inherently rms responding.
2. The response of a demodulating log amp depends on the waveform. Convention assumes that the input is sinusoidal. However, the AD606 is capable of accurately handling any input waveform, including ac voltages, pulses and square waves, Gaussian noise, and so on. See the AD640 data sheet, which covers the effect of waveform on logarithmic intercept, for more information.
3. The impedance in which the specified power is measured is not always stated. In the log amp context it is invariably assumed to be 50 Ω. Thus, 0 dBm means "1 mW rms in 50 Ω," and corresponds to an rms voltage of $\sqrt{(1\text{ mW} \times 50\ \Omega)}$, or 224 mV.

Popular convention requires the use of dBm to simplify the comparison of log amp specifications. Unless otherwise stated, sinusoidal inputs expressed as dBm in 50 Ω are used to specify the performance of the AD606 throughout this data sheet. We will also show the corresponding rms voltages where it helps to clarify the specification. Noise levels will likewise be given in dBm; the response to Gaussian noise is 0.5 dB higher than for a sinusoidal input of the same rms value.

Note that dynamic range, being a simple ratio, is always specified simply as "dB", and the slope of the logarithmic transfer function is correctly specified as "mV/dB," NOT as "mV/dBm."

LOGARITHMIC SLOPE AND INTERCEPT

A generalized logarithmic amplifier having an input voltage V_{IN} and output voltage V_{LOG} must satisfy a transfer function of the form

$$V_{LOG} = V_Y \log_{10}(V_{IN}/V_X)$$

where, in the case of the AD606, the voltage V_{IN} is the difference between the voltages on pins INHI and INLO, and the voltage V_{LOG} is that measured at the output pin VLOG. V_Y and V_X are fixed voltages that determine the slope and intercept of the logarithmic amplifier, respectively. These parameters are inherent in the design of a particular logarithmic amplifier, although may be adjustable, as in the AD606. When $V_{IN} = V_X$, the logarithmic argument is one, hence the logarithm is zero. V_X is, therefore, called the logarithmic *intercept* voltage because the output voltage V_{LOG} crosses zero for this input. The slope voltage V_Y is can also be interpreted as the "volts per decade" when using base-10 logarithms as shown here.

Note carefully that V_{LOG} and VLOG in the above paragraph (and elsewhere in this data sheet) are different. The first is a voltage; the second is a pin designation.

This equation suggests that the input V_{IN} is a dc quantity, and, if V_X is positive, that V_{IN} must likewise be positive, since the logarithm of a negative number has no simple meaning. In fact, in the AD606, *the response is independent of the sign of* V_{IN} because of the particular way in which the circuit is built. This is part of the demodulating nature of the amplifier, which results in an alternating input voltage being transformed into a quasi-dc (rectified and filtered) output voltage.

The single supply nature of the AD606 results in common-mode level of the inputs INHI and INLO being at about +2.5 V (using the recommended +5 V supply). In normal ac operation, this bias level is developed internally and the input signal is coupled in through dc-blocking capacitors. Any residual dc offset voltage in the first stage limits the logarithmic accuracy for small inputs. In ac operation, this offset is automatically and continuously nulled via a feedback path from the last stage, provided that the pins INHI and INLO are not shorted together, as would be the case if transformer coupling were used for the signal.

While any logarithmic amplifier must eventually conform to the basic equation shown above, which, with appropriate elaboration, can also fully account for the effect of the signal waveform on the effective intercept,[1] it is more convenient in RF applications to use a simpler expression. This simplification results from first, assuming that the input is always sinusoidal, and second, using a decibel representation for the input level. The standard representation of RF levels is (incorrectly, in a log amp context) in terms of power, specifically, decibels above 1 milliwatt (dBm) with a presumed impedance level of 50 Ω. That being the case, we can rewrite the transfer function as

$$V_{LOG} = V_Y (P_{IN} - P_X)$$

where it must be understood that P_{IN} means the sinusoidal input power level in a 50 Ω system, expressed in dBm, and P_X is the intercept, also expressed in dBm. In this case, P_{IN} and P_X are simple, dimensionless numbers. (P_X is sometimes called the "logarithmic offset," for reasons which are obvious from the above equation.) V_Y is still defined as the logarithmic slope, usually specified as so many millivolts per decibel, or mV/dB.

In the case of the AD606, the slope voltage, V_Y, is nominally 750 mV when operating at V_{POS} = 5 V. This can also be expressed as 37.5 mV/dB or 750 mV/decade; thus, the 80 dB range equates to 3 V. Figure 1 shows the transfer function of the AD606. The slope is closely proportional to V_{POS}, and can more generally be stated as $Y_Y = 0.15 \times V_{POS}$. Thus, in those applications where the scaling must be independent of supply voltage, this must be stabilized to the required accuracy. In applications where the output is applied to an A/D converter,

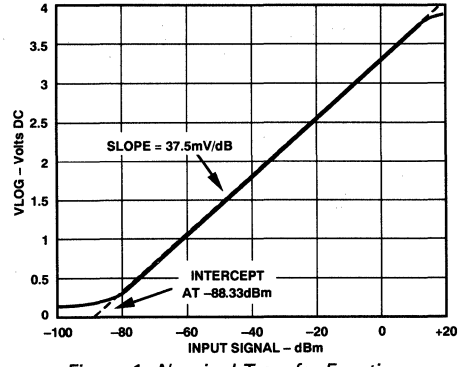

Figure 1. Nominal Transfer Function

[1]See, for example, the AD640 data sheet, which is published in Section 3 of the *Special Linear Reference Manual* or Section 9.3 of the *1992 Amplifier Applications Guide*.

the reference for that converter should be a fractional part of V_{POS}, if possible. The slope is essentially independent of temperature.

The intercept P_X is essentially independent of either the supply voltage or temperature. However, the AD606 is not factory-calibrated, and both the slope and intercept may need to be externally adjusted. Following calibration, the conformance to an ideal logarithmic law will be found to be very close, particularly at moderate frequencies (see Figure 14), and still acceptable at the upper end of the frequency range (Figure 15).

CIRCUIT DESCRIPTION

Figure 2 is a block diagram of the AD606, which is a complete logarithmic amplifier system in monolithic form. It uses a total of nine limiting amplifiers in a "successive detection" scheme to closely approximate a logarithmic response over a total dynamic range of 90 dB (Figure 2). The signal input is differential, at nodes INHI and INLO, and will usually be sinusoidal and ac coupled. The source may be either differential or single-sided; the input impedance is about 2.5 kΩ in parallel with 2 pF. Seven of the amplifier/detector stages handle inputs from −80 dBm (32 μV rms) up to about −14 dBm (45 mV rms). The noise floor is about −83 dBm (18 μV rms). Another two stages receive the input attenuated by 22.3 dB, and respond to inputs up to +10 dBm (707 mV rms). The gain of each of these stages is 11.15 dB and is accurately stabilized over temperature by a precise biasing system.

The detectors provide full-wave rectification of the alternating signal present at each limiter output. Their outputs are in the form of currents, proportional to the supply voltage. Each cell incorporates a low-pass filter pole, as the first step in recovering the average value of the demodulated signal, which contains appreciable energy at even harmonics of the input frequency. A further real pole can be introduced by adding a capacitor between the summing node ISUM and VPOS. The summed detector output currents are applied to a 6:1 reduction current mirror. Its output at ILOG is scaled 2 μA/dB, and is converted to voltage by an internal load resistor of 9.375 kΩ between ILOG and OPCM (output common, which is usually grounded). The nominal slope at this point is 18.75 mV/dB (375 mV/decade).

In applications where V_{LOG} is taken to an A/D converter which allows the use of an external reference, this reference input should also be connected to the same +5 V supply. The power-supply voltage may be in the range +4.5 V to +5.5 V, providing a range of slopes from nominally 33.75 mV/dB (675 mV/decade) to 41.25 mV/dB (825 mV/decade).

A buffer amplifier, having a gain of two, provides a final output scaling at V_{LOG} of 37.5 mV/dB (750 mV/decade). This low-impedance output can run from close to ground to over +4 V (using the recommended +5 V supply) and is tolerant of resistive and capacitive loads. Further filtering is provided by a conjugate pole pair, formed by internal capacitors which are an integral part of the output buffer. The corner frequency of the overall filter is 2 MHz, and the 10%–90% rise time is 150 ns. Later, we will show how the slope and intercept can be altered using simple external adjustments. The direct buffer input BFIN is used in these cases.

The last limiter output is available as complementary currents from open collectors at pins LMHI and LMLO. These currents are each 1.2 mA typical with LADJ grounded and may be converted to voltages using external load resistors connected to VPOS; typically, a 200 Ω resistor is used on just one output. The voltage gain is then over 90 dB, resulting in a hard-limited output for all input levels down to the noise floor. The phasing is such that the voltage at LMHI goes high when the input (INHI to INLO) is positive. The overall delay time from the signal inputs to the limiter outputs is 8 ns. Of particular importance is the phase stability of these outputs versus input level. At 50 MHz, the phase typically remains within ±4° from −70 dBm to +5 dBm. The rise time of this output (essentially a square wave) is about 1.2 ns, resulting in clean operation to more than 70 MHz.

Offset-Control Loop

The offset-control loop nulls the input offset voltage, and sets up the bias voltages at the input pins INHI and INLO. A full understanding of this offset-control loop is useful, particularly

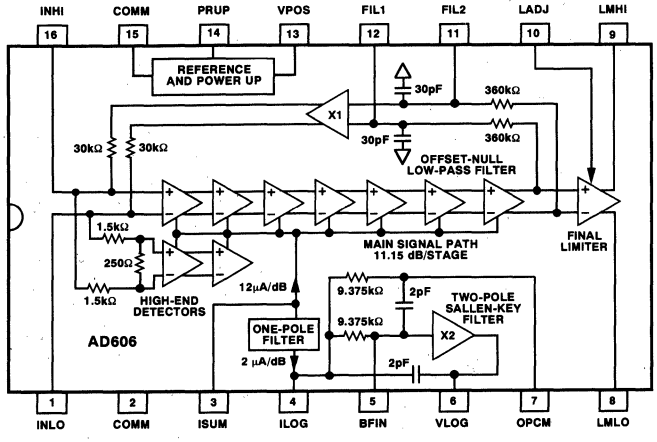

Figure 2. AD606 Simplified Block Diagram

when using larger input coupling capacitors and an external filter capacitor to lower the minimum acceptable operating frequency. The loop's primary purpose is to extend the lower end of the dynamic range in the case where the offset voltage of the first stage should be high enough to cause later stages to prematurely enter limiting, because of the high dc gain (about 8000) of the main amplifier system. For example, an offset voltage of only 20 μV would become 160 mV at the output of the last stage in the main amplifier (before the final limiter section), driving the last stage well into limiting. In the absence of noise, this limiting would simply result in the logarithmic output ceasing to become any lower below a certain signal level at the input. The offset would also degrade the logarithmic conformance in this region. In practice, the finite noise of the first stage also plays a role in this regard, even if the dc offset were zero.

Figure 3 shows a representation of this loop, reduced to essentials. The figure closely corresponds to the internal circuitry, and correctly shows the input resistance. Thus, the forward gain of the main amplifier section is 7 × 11.15 dB, but the loop gain is lowered because of the attenuation in the network formed by

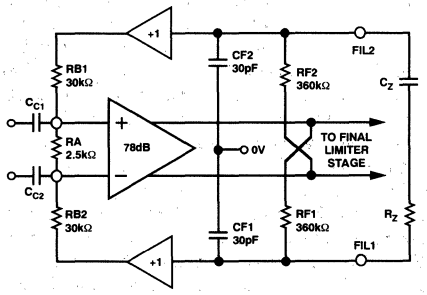

Figure 3. Offset Control Loop

RB1 and RB2 and the input resistance RA. The connection polarity is such as to result in negative feedback, which reduces the input offset voltage by the dc loop gain, here about 50 dB, that is, by a factor of about 316. We use a *differential* representation, because later we will examine the consequences to the power-up response time in the event that the ac coupling capacitors C_{C1} and C_{C2} do not exactly match. Note that these capacitors, as well as forming a high-pass filter to the signal in the forward path, also introduce a pole in the feedback path.

Internal resistors RF1 and RF2 in conjunction with grounded capacitors CF1 and CF2 form a low-pass filter at 15 kHz. This frequency can optionally be lowered by the addition of an external capacitor C_Z, and in some cases a series resistor R_Z. This, in conjunction with the low-pass section formed at the input coupling, results in a two-pole high-pass response, falling of at 40 dB/decade below the corner frequency. The damping factor of this filter depends on the ratio C_Z/C_C (when $C_Z >> C_F$) and also on the value of R_Z.

The inclusion of this control loop has no effect on the high frequency response of the AD606. Nor does it have any effect on the low frequency response when the input amplitude is substantially above the input offset voltage.

The loop's effect is felt only at the lower end of the dynamic range, that is, from about −80 dBm to −70 dBm, and when the signal frequency is near the lower edge of the passband. Thus, the small signal results which are obtained using the suggested model are not indicative of the ac response at moderate to high signal levels. Figure 4 shows the response of this model for the default case (using C_C = 100 pF and C_Z = 0) and with C_Z = 150 pF. In general, a *maximally flat ac* response occurs when C_Z is roughly twice C_C (making due allowance for the internal 30 pF capacitors). Thus, for audio applications, one can use C_C = 2.7 μF and C_Z = 4.7 μF to achieve a high-pass corner (−3 dB) at 25 Hz.

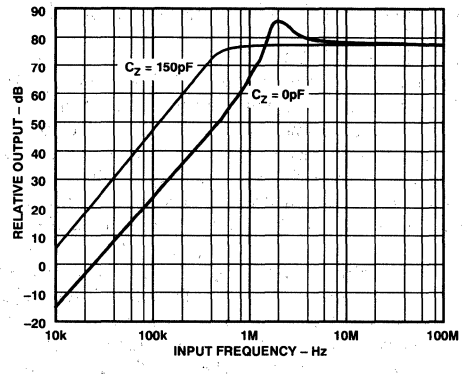

Figure 4. Frequency Response of Offset Control Loop for C_Z = 0 pF and C_Z = 150 pF (C_C = 100 pF)

However, the maximally flat ac response is not optimal in two special cases. First, where the RF input level is rapidly pulsed, the fast edges will cause the loop filter to ring. Second, ringing can also occur when using the power-up feature, and the ac coupling capacitors do not exactly match in value. We will examine the latter case in a moment. Ringing in a linear amplifier is annoying, but in a log amp, with its much enhanced sensitivity to near zero signals, it can be very disruptive.

To optimize the low level accuracy, that is, achieve a highly-damped pulse response in this filter, it is recommended to include a resistor R_Z in series with an increased value of C_Z. Some experimentation may be necessary, but for operation in the range 3 MHz to 70 MHz, values of C_C = 100 pF, C_Z = 1 nF and R_Z = 2 kΩ are near optimal. For operation down to 100 kHz use C_C = 10 nF, C_Z = 0.1 μF and R_Z = 13 kΩ. Figure 5 shows typical connections for the AD606 with these filter components added.

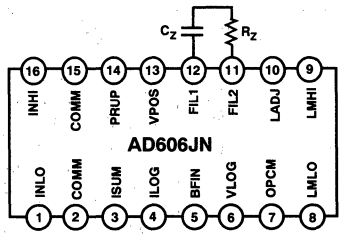

Figure 5. Use of C_Z and R_Z for Offset Control Loop Compensation

For operation above 10 MHz, it is not necessary to add the external capacitors CF1, CF2, and C_Z, although an improvement in low frequency noise can be achieved by so doing (see

APPLICATIONS). Note that the offset control loop does not materially affect the low-frequency cutoff at high input levels, when the offset voltage is swamped by the signal.

Power-Up Interface

The AD606 features a power-saving mode, controlled by the logic level at Pin 14 (PRUP). When powered down, the quiescent current is typically 65 μA, or about 325 μW. A CMOS logical HIGH applied to PRUP activates both internal references, and the system becomes fully functional within about 3.5 μs. When this input is a CMOS logical LOW, the system shuts down to the quiescent level within about 5 μs.

The power-up time is somewhat dependent on the signal level and can be degraded by mismatch of the input coupling capacitors. The explanation is as follows. When the AD606 makes the transition from powered-down to fully active, the dc bias voltage at the input nodes INHI and INLO (about +2.5 V) inevitably changes slightly, as base current in the input transistors flows in the bias resistors. In fact, first-order correction for this is included in the specially designed offset buffer amplifier, but even a few millivolts of change at these inputs represents a significant equivalent "dBm" level.

Now, if the coupling capacitors do not match exactly, some fractional part of this residual voltage step becomes coupled into the amplifier. For example, if there is a 10 % capacitor mismatch, and INHI and INLO jump 20 mV at power-up, there is a 2 mV pulse input to the system, which may cause the offset control loop to ring. Note that 2 mV is roughly 40 times greater than the amplitude of a sinusoidal input at –75 dBm. As long as the ringing persists, the AD606 will be "blind" to the actual input, and V_{LOG} will show major disturbances.

The solution to this problem is first, to ensure that the loop filter does not ring, and second, to use well-matched capacitors at the signal input. Use the component values suggested above to minimize ringing.

APPLICATIONS

Note that the AD606 has more than 70 MHz of input bandwidth and 90 dB of gain! Careful shielding is needed to realize its full dynamic range, since nearly all application sites will be pervaded by many kinds of interference, radio and TV stations, etc., all of which the AD606 faithfully hears. In bench evaluation, we recommend placing all of the components in a shielded box and using feedthrough decoupling networks for the supply voltage. In many applications, the AD606's low power drain allows the use of a 6 V battery inside the box.

Basic RSSI Application

Figure 6 shows the basic RSSI (Receiver Signal Strength Indicator) application circuit, including the calibration adjustments, either or both of which may be omitted in noncritical applications. This circuit may be used "as is" in such measurement applications as the log/IF strip in a spectrum or network analyzer or, with the addition of an FM or QPSK demodulator fed by the limiter outputs, as an IF strip in such communications applications as a GSM digital mobile radio or FM receiver.

The slope adjustment works in this way: the buffer amplifier (which forms part of a Sallen-Key two-pole filter, see Figure 2) has a dc gain of plus two, and the resistance from BFIN (buffer in) to OPCM (output common) is nominally 9.375 kΩ. This resistance is driven from the logarithmic detector sections with a current scaled 2 μA/dB, generating 18.75 mV/dB at BFIN, hence 37.5 mV/dB at V_{LOG}. Now, a resistor (R4 in Figure 6) connected directly between BFIN and VLOG would form a controlled positive-feedback network with the internal 9.375 kΩ resistor which would raise the gain, and thus increase the slope voltage, while the same external resistor connected between BFIN and ground would form a shunt across the internal resistor and reduce the slope voltage. By connecting R4 to a potentiometer R2 across the output, the slope may be adjusted either way; the value for R4 shown in Figure 6 provides approximately ±10% range, with essentially no effect on the slope at the midposition.

The intercept may be adjusted by adding a small current into BFIN via R1 and R3. The AD606 is designed to have the nominal intercept value of –88 dBm when R1 is centered using this network, which provides a range of ±5 dB.

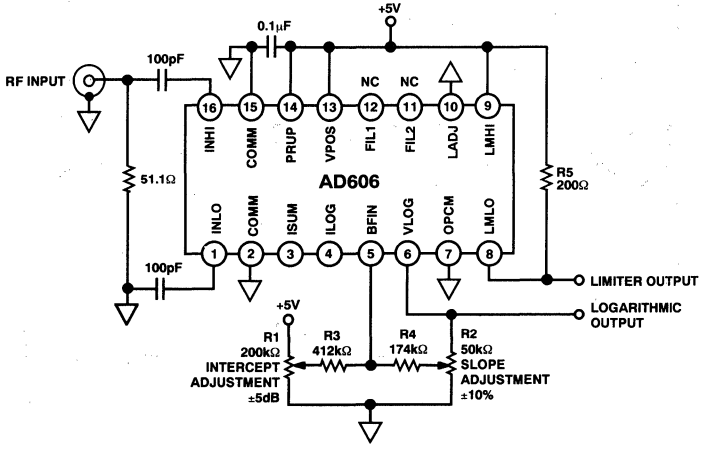

Figure 6. Basic Application Circuit Showing Optional Slope and Intercept Adjustments

Adjustment Procedure

The slope and intercept adjustments interact; this can be minimized by reducing the resistance of R1 and R2, chosen here to minimize power drain. Calibration can be achieved in several ways: The simplest is to apply an RF input at the desired operating frequency which is amplitude modulated at a relatively low frequency (say 1 kHz to 10 kHz) to a known modulation index. Thus, one might choose a ratio of 2 between the maximum and minimum levels of the RF amplitude, corresponding to a 6 dB (strictly, 6.02 dB) change in input level. The average RF level should be set to about −35 dBm (the midpoint of the AD606's range). R2 is then adjusted so that the 6 dB input change results in the desired output voltage change, for example, 226 mV at 37.5 mV/dB.

A better choice would be a 4:1 ratio (12.04 dB), to spread the residual error out over a larger segment of the whole transfer function. If a pulsed RF generator is available, the decibel increment might be enlarged to 20 dB or more. Using just a fixed-level RF generator, the procedure is more time consuming, but is carried out in just the same way: manually change the level by a known number of decibels and adjust R2 until V_{LOG} varies by the corresponding voltage.

Having adjusted the slope, the intercept may now be simply adjusted using a known input level. A value of –35 dBm (397.6 mV rms, or 400 mV to within 0.05 dB) is recommended, and if the standard scaling is used (P_X = – 88.33 dBm, V_Y = 37.5 mV/dB), then V_{LOG} should be set to +2 V at this input level.

A Low Cost Audio Through RF Power Meter

Figure 7 shows a simple power meter that uses the AD606 and an ICL7136 3-1/2 digit DMM IC driving an LCD readout. The circuit operates from a single +5 V supply and provides direct readout in dBm, with a resolution of 0.1 dBm.

In contrast to the limited dynamic range of the diode and thermistor-styled sensors used in power meters, the AD606 can measure signals from below −80 dBm to over +10 dBm. An optional 50 Ω termination is included in the figure; this could form the lower arm of an external attenuator to accommodate larger signal levels. By the simple expedient of using a 13 dB attenuator, the LCD reading now becomes dBV (decibels above 1 V rms). This requires a series resistor of 174 Ω, presenting an input resistance of 224 Ω. Alternatively, the input resistance can be raised to 600 Ω using 464 Ω and 133 Ω. It is important to note that the AD606 inputs must be ac coupled. To extend the low frequency range, use larger coupling capacitors and an external loop filter, as outlined earlier.

The nominal 0.5 V to 3.5 V output of the AD606 (for a −75 dBm to +5 dBm input) must be scaled and level shifted to fit within the +1 V to +4.5 V common-mode range of the ICL7136 for the +5 V supply used. This is achieved by the passive resistor network of R1, R2, and R3 in conjunction with the bias networks of R4 through R7, which provide the ICL7136 with its reference voltage, and R9 through R11, which set the intercept. The ICL7136 measures the differential voltage between IN HI and IN LO, which ranges from −75 mV to +5 mV for a −75 dBm to +5 dBm input.

To calibrate the power meter, first adjust R6 for 100 mV between REF HI and REF LO. This sets the initial slope. Then adjust R10 to set IN LO 80 mV higher than IN HI. This sets the initial intercept. The slope and intercept may now be adjusted using a calibrated signal generator as outlined in the previous section.

To extend the low frequency limit of the system to audio frequencies, simply change C1, C2, and C3 to 4.7 μF.

The limiter output of the AD606 may be used to drive the high-impedance input of a frequency counter.

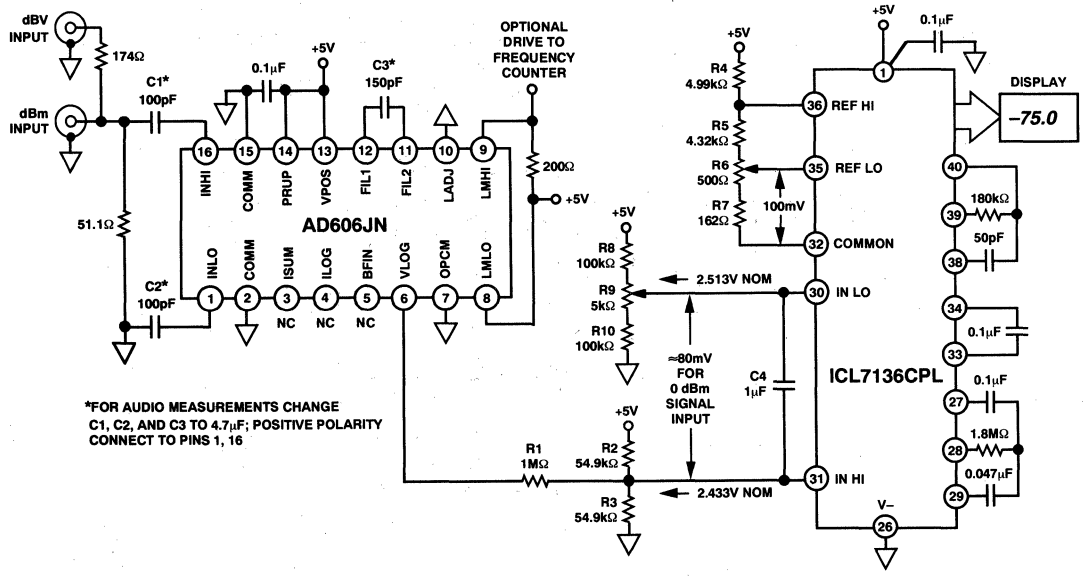

Figure 7. A Low Cost RF Power Meter

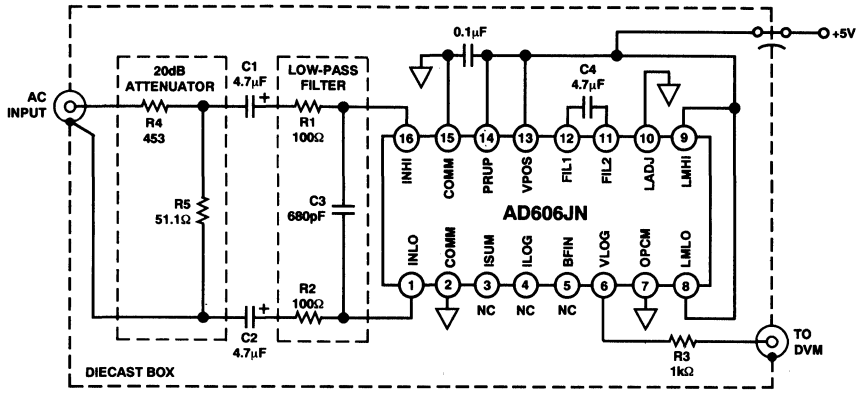

Figure 8. Circuit for Low Frequency Measurements

Low Frequency Applications

With reasonably sized input coupling capacitors and an optional input low-pass filter, the AD606 can operate to frequencies as low as 200 Hz with good log conformance. Figure 8 shows the schematic, with the low-pass filter included in the dashed box. This circuit should be built inside a die cast box and the signal brought in through a coaxial connector. The circuit must also have a low-pass filter to reject the attenuated RF signals that would otherwise be rectified along with the desired signal and be added to the log output. The shielded and filtered circuit has a 90 dB dynamic range, as shown in Figure 9.

In this circuit, R4 and R5 form a 20 dB attenuator that extends the input range to 10 V rms. R3 isolates loads from VLOG. Capacitors C1 and C2 (4.7 μF each), R1, R2, and the AD606's input resistance of 2.5 kΩ form a 100 Hz high-pass filter that is before the AD606; the corner frequency of this filter must be well below the lowest frequency of interest. In addition, the offset-correction loop introduces another pole at low signal levels that is transformed into another high-pass filter because it is in a feedback path. This indicates that there has to be a gradual transition from a 40 dB roll off at low signal levels to a 20 dB roll off at high signal levels, at which point the feedback low pass filter is effectively disabled since the incoming signal swamps the feedback signal.

This low-pass filter introduces some attenuation due to R1 and R2 in conjunction with the 2.5 kΩ input resistance of the AD606. To minimize this effect, the value of R1 and R2 should be kept as small as possible–100 Ω is a good value since it balances the need to reduce the attenuation as mentioned above with the requirement for R1 and R2 to be much larger then the impedance of C1 and C2 at the low-pass corner frequency, in our case about 1 MHz.

20

DC Coupled Demodulating 120MHz Logarithmic Amplifier

AD640

FEATURES

Complete, Fully Calibrated Monolithic System
Five Stages, Each Having 10dB Gain, 350MHz BW
Direct Coupled Fully Differential Signal Path
Logarithmic Slope, Intercept and AC Response are Stable Over Full Military Temperature Range
Dual Polarity Current Outputs Scaled 1mA/Decade
Voltage Slope Options (1V/Decade, 100mV/dB, etc.)
Low Power Operation (Typically 220mW at ±5V)
Low Cost Plastic Packages Also Available

APPLICATIONS

Radar, Sonar, Ultrasonic and Audio Systems
Precision Instrumentation from DC to 120MHz
Power Measurement with Absolute Calibration
Wide Range High Accuracy Signal Compression
Alternative to Discrete and Hybrid IF Strips
Replaces Several Discrete Log Amp ICs

PRODUCT DESCRIPTION

The AD640 is a complete monolithic logarithmic amplifier. A single AD640 provides up to 50dB of dynamic range for frequencies from dc to 120MHz. Two AD640s in cascade can provide up to 95dB of dynamic range at reduced bandwidth. The AD640 uses a successive detection scheme to provide an output current proportional to the logarithm of the input voltage. It is laser calibrated to close tolerances and maintains high accuracy over the full military temperature range using supply voltages from ±4.5V to ±7.5V.

The AD640 comprises five cascaded dc coupled amplifier/limiter stages, each having a small signal voltage gain of 10dB and a −3dB bandwidth of 350MHz. Each stage has an associated full-wave detector, whose output current depends on the absolute value of its input voltage. The five outputs are summed to provide the video output (when low pass filtered) scaled at 1mA per decade (50μA per dB). On chip resistors can be used to convert this output current to a voltage with several convenient slope options. A balanced signal output at +50dB (referred to input) is provided to operate AD640s in cascade.

The logarithmic response is absolutely calibrated to within ±1dB for dc or square wave inputs from ±0.75mV to ±200mV, with an intercept (logarithmic offset) at 1mV dc. An integral X10 attenuator provides an alternative input range of ±7.5mV to ±2V dc. Scaling is also guaranteed for sinusoidal inputs.

The AD640B is specified for the industrial temperature range of −40°C to +85°C and the AD640T, available processed to MIL-STD-883B, for the military range of −55°C to +125°C. Both are available in 20-pin side brazed ceramic DIPs or leadless chip carriers (LCC). The AD640J is specified for the commercial temperature range of 0 to +70°C, and is available in both 20-pin plastic DIP (N) and PLCC (P) packages.

This device is now available to Standard Military Drawing (DESC) number 5962-9095501MRA and 5962-9095501M2A.

PRODUCT HIGHLIGHTS

1. Absolute calibration of a wideband logarithmic amplifier is unique. The AD640 is a high accuracy measurement device, not simply a logarithmic building block.
2. Advanced design results in unprecedented stability over the full military temperature range.
3. The fully differential signal path greatly reduces the risk of instability due to inadequate power supply decoupling and shared ground connections, a serious problem with commonly used unbalanced designs.
4. Differential interfaces also ensure that the appropriate ground connection can be chosen for each signal port. They further increase versatility and simplify applications. The signal input impedance is ~500kΩ in shunt with ~2pF.
5. The dc coupled signal path eliminates the need for numerous interstage coupling capacitors and simplifies logarithmic conversion of subsonic signals.
6. The low input offset voltage of 50μV (200μV max) ensures good accuracy for low level dc inputs.
7. Thermal recovery "tails," which can obscure the response when a small signal immediately follows a high level input, have been minimized by special attention to design details.
8. The noise spectral density of $2nV/\sqrt{Hz}$ results in a noise floor of ~23μV rms (−80dBm) at a bandwidth of 100MHz. The dynamic range using cascaded AD640s can be extended to 95dB by the inclusion of a simple filter between the two devices.

NOTES

[1]Logarithms to base 10 are used throughout. The response is independent of the sign of V_{IN}.

[2]Attenuation ratio trimmed to calibrate intercept to 10mV when in use. It has a temperature coefficient of +0.3%/°C.

[3]The zero-signal current is a function of temperature unless internal temperature compensation (ITC) pin is grounded.

[4]Overall gain is trimmed using a ±200μV square wave at 2kHz, corrected for the onset of compression.

[5]The fully limited signal output will appear to be a square wave; its amplitude is proportional to absolute temperature.

[6]Currents defined as flowing *into* Pin 14. See FUNDAMENTALS OF LOGARITHMIC CONVERSION for full explanation of scaling concepts. Slope is measured by linear regression over central region of transfer function.

[7]The logarithmic intercept in dBV (decibels relative to 1V) is defined as 20 LOG_{10} (V_X/1V).

[8]Operating in circuit of Figure 24 using ±0.1% accurate values for R_{LA} and R_{LB}. Includes slope and nonlinearity errors. Input offset errors also included for V_{IN} >3mV dc, and over the full input range in ac applications.

[9]Essentially independent of supply voltages.

[10]Using the circuit of Figure 27, using cascaded AD640s and offset nulling. Input is sinusoidal, 0dBm in 50Ω=223mV rms.

[11]For a sinusoidal signal (see EFFECT OF WAVEFORM ON INTERCEPT). Pin 8 on second AD640 must be grounded to ensure temperature stability of intercept for dual AD640 system.

[12]Using the circuit of Figure 24, using single AD640 and offset nulling. Input is sinusoidal, 0dBm in 50Ω=223mV rms.

[13]Using the circuit of Figure 32, using cascaded AD640s and attenuator. Square wave input.

[14]For outline information see Package Information section.

All min and max specifications are guaranteed, but only those in **boldface** are 100% tested on all production units. Results from those tests are used to calculate outgoing quality levels.

Low Power Mixer/AGC/RSSI 3 V Receiver IF Subsystem

AD607

FEATURES

Complete Receiver on a Chip: Monoceiver™
Interfaces to AD7015 GSM Baseband Converter
Mixer
- **–15 dBm 1 dB Compression Point**
- **>450 MHz Input Bandwidth**
- **–16 dBm LO Input**

Linear IF Amplifier
- **100 dB of Linear-in-dB Gain Control**
- **Internal AGC with RSSI Output or External MGC**
- **Any IF Below 25 MHz**

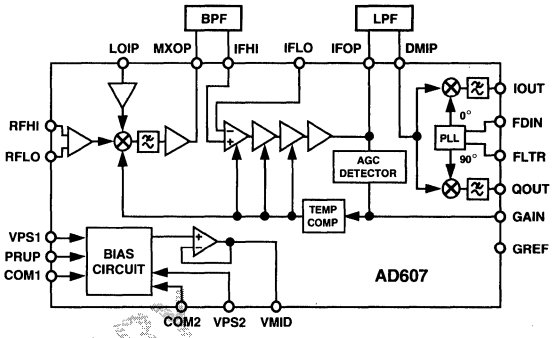
Quadrature Demodulator
- **On-Board Phase-Locked Quadrature Oscillator**
- **90 ± 1.5° Phase Quadrature at 10.7 MHz**
- **Can Also Demodulate AM, FM, CW, SSB**

Low Power
- **25 mW at 3 V**
- **CMOS-Compatible Power-Down to 300 µW**

APPLICATIONS

GSM, CDMA, PHP, TDMA Receivers
Infrared Data Receivers
Battery-Powered Communications Receivers

FUNCTIONAL BLOCK DIAGRAM



GENERAL DESCRIPTION

The AD607 is a 3 V low power receiver RF/IF subsystem for operation at IF or RF input frequencies as high as 450 MHz and IFs to 25 MHz. It consists of a mixer, IF amplifiers, an I/Q demodulator, a phase-locked quadrature oscillator, AGC detector, and a biasing system with external power-down. In a typical DMR application, the AD607 accepts a 240 MHz IF input and downconverts it to a 10.7 MHz IF where it is filtered, amplified with internal AGC (or external MGC), and demodulated into I and Q baseband outputs.

The AD607's low noise, high intercept mixer is a doubly balanced "Gilbert-Cell" type and operates linearly for RF inputs spanning –95 dBm to –15 dBm. It has a nominal –5 dBm third-order intercept. The mixer section of the AD607 also includes a local oscillator (LO) preamplifier, which lowers the required LO drive to –16 dBm (50 mV sine wave amplitude).

Fully differential access to the RF input increases the versatility of this front end for such applications as interfacing to differential output SAW filters. The mixer's single-sided IF current output can directly drive a bandpass filter with an impedance of 200 Ω or greater. An optional second IF filter can be included to limit wideband noise and provide additional selectivity. The output for the second IF filter can optionally be used to drive an A/D converter or the AD607's PLL, as will be described below.

The gain control input (Pin 12) can serve as either an MGC input or an RSSI (AGC voltage) output. In MGC operation, the AD607 accepts a DSP-based MGC input of 0 V to 2 V at pin 12. This voltage can be generated by a DAC in the compatible AD70xx family of baseband converters. In AGC operation, an on-board detector and an external averaging capacitor connected to Pin 12 form an AGC loop that holds the I and Q output levels at about ±300 mV. The voltage across this capacitor then provides an RSSI output.

An I/Q demodulator provides in-phase and quadrature baseband outputs to interface with such baseband converters as the Analog Devices' AD7002, AD7005, AD7013, or AD7015. A unique quadrature VCO that is phase-locked to a low level or CMOS-compatible input at the intermediate frequency drives the I and Q demodulator.

The I/Q demodulator can also demodulate AM or FM when its oscillator is phase locked to the received signal; in this mode, the In-Phase and Quadrature demodulators become detectors for AM and FM, respectively. The oscillator can also be phase-locked to an external oscillator and the demodulator will act as a product detector for CW or SSB reception.

The AD607 uses supply voltages from 2.7 V to 6 V over the temperature range of –25°C to +85°C. Operation is enabled by a CMOS logical level; response time is typically <3 µs. When disabled the standby power is reduced to 300 µW. The AD607 comes in a 20-pin Small-Shrink Outline (SSOP) surface-mount package.

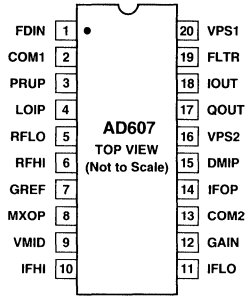
PIN CONNECTION

20-Lead SSOP



PIN DESCRIPTION

Pin	Mnemonic	Reads	Function
1	FDIN	Frequency Demodulator Input	PLL input for I/Q demodulator quadrature oscillator.
2	COM1	Common #1	Supply common for RF front end and main bias.
3	PRUP	Power-Up	3 V/5 V CMOS-compatible power-up control.
4	LOIP	Local Oscillator Input	LO external input.
5	RFLO	RF "Low" Input	Usually connected to ac ground.
6	RFHI	RF "High" Input	Accepts RF input of –95 dBm to –15 dBm.
7	GREF	Gain Reference	High impedance input, typically 1.5 V, sets gain scaling.
8	MXOP	Mixer Output	Low impedance, single-sided voltage output, +5 dBm max.
9	VMID	Mid-Supply Bias Voltage Output	Output of the mid-supply bias generator (VPOS/2).
10	IFHI	IF "High" Input	IF input, +5 dBm (±56 mV) max.
11	IFLO	IF "Low" Voltage	Reference node for IF input; auto-offset null.
12	GAIN	Gain Control Input	High impedance input, 0 V–2 V, max gain at V = 0.
13	COM2	Common #2	Supply common for IF stages and demodulator.
14	IFOP	IF Output	Low impedance, single-sided voltage output, +5 dBm max.
15	DMIP	Demodulator Input	Signal input to I and Q demodulators.
16	VPS2	VPOS Supply #2	Supply to high level IF, PLL, and demodulators.
17	QOUT	Quadrature Output	Low impedance Q baseband output, ±1.23 V full scale.
18	IOUT	In-Phase Output	Low impedance I baseband output, ±1.23 V full scale.
19	FLTR	PLL Loop Filter	Series RC PLL Loop filter connected to ground.
20	VPS1	VPOS Supply #1	Supply to mixer, low level IF, PLL, and gain control.

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the AD607 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

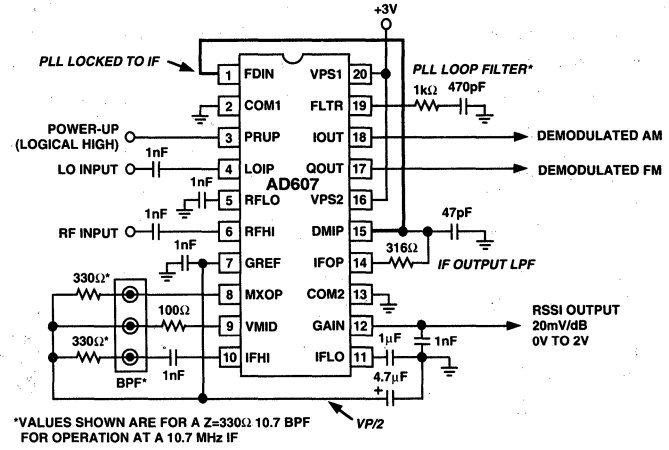

Figure 3. AD607 Connections for AM or FM Demodulation. The PLL Recovers the Received Carrier via the Connection (Darker Line) Between Pins 1 and 15. The AD607's Internal AGC Circuit Controls the Gain and Provides an RSSI Output at Pin 12

Low Power Mixer/Limiter/RSSI 3 V Receiver IF Subsystem

AD608

FEATURES

Mixer
- **–15 dBm, 1 dB Compression Point**
- **–5 dBm IP3**
- **26 dB Conversion Gain**
- **>450 MHz Input Bandwidth**

Logarithmic/Limiting Amplifier
- **90 dB RSSI Range**
- **±3° Phase Stability over 80 dB Range**

Low Power
- **21 mW at 3 V Power Consumption**
- **CMOS-Compatible Power-Down to 200 μW typ**
- **150 ns Enable/Disable Time**

APPLICATIONS
- **Low Power PHP, GSM, TDMA, FM, or PM Receivers**
- **Battery-Powered Instrumentation**

GENERAL DESCRIPTION

The AD608 provides both a low power, low distortion, low noise mixer and a complete, monolithic logarithmic/limiting amplifier using a "successive-detection" technique. It provides both a high speed RSSI (Received Signal Strength Indicator) output with 90 dB dynamic range and a hard-limited output. The RSSI output is from a two-pole post demodulation low-pass filter and provides a loadable output voltage of +0.2 V to +2 V. The AD608 operates from a single 2.7 V to 6 V supply at a typical power level of 21 mW at 3 V.

The RF and LO bandwidths both exceed 450 MHz. In a typical IF application, the AD608 will accept the output of a 240 MHz SAW filter and downconvert it to a nominal 10.7 MHz IF with a conversion gain of 26 dB (Z_{IF} = 165 Ω). The AD608's logarithmic/limiting amplifier section handles any IF from LF to as high as 50 MHz.

The mixer is a doubly balanced "Gilbert-Cell" type and operates linearly for RF inputs spanning –95 dBm to –15 dBm. It has a nominal –5 dBm third-order intercept. An on-board LO preamplifier requires only –6 dBm of LO drive. The mixer's current output drives a reverse-terminated, industry-standard 10.7 MHz, 330 Ω filter and can drive reverse-terminated filter impedances as low as 220 Ω.

The nominal logarithmic scaling is such that the output is +0.2 V for a sinusoidal input of –75 dBm and +2.0 V at an input of +15 dBm; over this range the logarithmic conformance is typically ±1 dB. The logarithmic slope is proportional to the supply voltage. A feedback loop automatically nulls the input offset of the first stage down to the submicrovolt level.

The AD608's limiter output provides a hard-limited signal output at 400 mV p-p. The voltage gain of the limiting amplifier to this output is more than 100 dB. Transition times are 7 ns, and the phase is stable to within ±3° at 10.7 MHz for signals from –75 dBm to +15 dBm.

It is enabled by a CMOS logic-level voltage input, with a response time of 150 ns. When disabled, the standby power is reduced to 200 μW within 400 ns.

The AD608 is specified for the industrial temperature range of –25°C to +85°C and is available in 16-pin plastic SOICs.

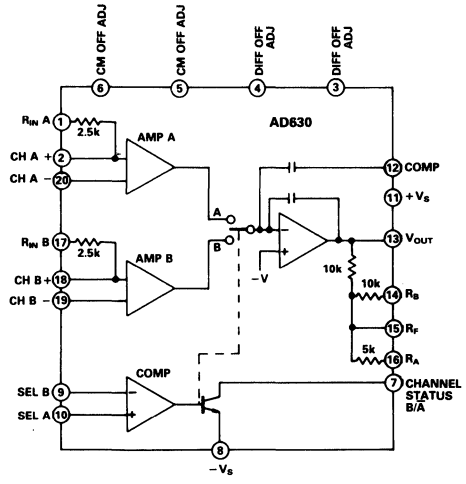
Balanced Modulator/Demodulator

AD630

FEATURES

Recovers Signal from +100dB Noise
2MHz Channel Bandwidth
45V/μs Slew Rate
−120dB Crosstalk @ 1kHz
Pin Programmable Closed Loop Gains of ±1 and ±2
0.05% Closed Loop Gain Accuracy and Match
100μV Channel Offset Voltage (AD630BD)
350kHz Full Power Bandwidth
Chips Available

FUNCTIONAL BLOCK DIAGRAM



PRODUCT DESCRIPTION

The AD630 is a high precision balanced modulator which combines a flexible commutating architecture with the accuracy and temperature stability afforded by laser wafer trimmed thin film resistors. Its signal processing applications include balanced modulation and demodulation, synchronous detection, phase detection, quadrature detection, phase sensitive detection, lock-in amplification and square wave multiplication. A network of on-board applications resistors provides precision closed loop gains of ±1 and ±2 with 0.05% accuracy (AD630B). These resistors may also be used to accurately configure multiplexer gains of +1, +2, +3 or +4. Alternatively, external feedback may be employed allowing the designer to implement his own high gain or complex switched feedback topologies.

The AD630 may be thought of as a precision op amp with two independent differential input stages and a precision comparator which is used to select the active front end. The rapid response time of this comparator coupled with the high slew rate and fast settling of the linear amplifiers minimize switching distortion. In addition, the AD630 has extremely low crosstalk between channels of −100dB @ 10kHz.

The AD630 is intended for use in precision signal processing and instrumentation applications requiring wide dynamic range. When used as a synchronous demodulator in a lock-in amplifier configuration, it can recover a small signal from 100dB of interfering noise (see lock-in amplifier application). Although optimized for operation up to 1kHz, the circuit is useful at frequencies up to several hundred kilohertz.

Other features of the AD630 include pin programmable frequency compensation, optional input bias current compensation resistors, common mode and differential offset voltage adjustment, and a channel status output which indicates which of the two differential inputs is active. This device is now available to Standard Military Drawing (DESC) numbers 5962–8980701RA and 5962–89807012A.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

PRODUCT HIGHLIGHTS

1. The configuration of the AD630 makes it ideal for signal processing applications such as: balanced modulation and demodulation, lock-in amplification, phase detection, and square wave multiplication.
2. The application flexibility of the AD630 makes it the best choice for many applications requiring precisely fixed gain, switched gain, multiplexing, integrating-switching functions, and high-speed precision amplification.
3. The 100dB dynamic range of the AD630 exceeds that of any hybrid or IC balanced modulator/demodulator and is comparable to that of costly signal processing instruments.
4. The op-amp format of the AD630 ensures easy implementation of high gain or complex switched feedback functions. The application resistors facilitate the implementation of most common applications with no additional parts.
5. The AD630 can be used as a two channel multiplexer with gains of +1, +2, +3 or +4. The channel separation of 100dB @ 10kHz approaches the limit which is achievable with an empty IC package.
6. The AD630 has pin-strappable frequency compensation (no external capacitor required) for stable operation at unity gain without sacrificing dynamic performance at higher gains.
7. Laser trimming of comparator and amplifying channel offsets eliminates the need for external nulling in most cases.

RGB to NTSC/PAL Encoders

AD720/AD721

FEATURES

Composite Video Output
Chrominance and Luminance (S-Video) Outputs
No External Filters or Delay Lines Required
Drives 75 Ω Reverse-Terminated Loads
Compact 28-Pin PLCC
Logic Selectable NTSC or PAL Encoding Modes
Automatically Selects Proper Chrominance Filter Cutoff Frequency for Encoding Standard
Logic Selectable Encode or Power-Down Mode (AD720 Only)
Logic Selectable Encode or Bypass Mode (AD721 Only)
Low Power: 200 mW typical

APPLICATIONS

RGB to NTSC or PAL Encoding
Drive RGB Signals into 75 Ω Load (AD721 Only)

PRODUCT DESCRIPTION

The AD720 and AD721 RGB to NTSC/PAL Encoders convert red, green and blue color component signals into their corresponding luminance (baseband amplitude) and chrominance (subcarrier amplitude and phase) signals in accordance with either NTSC or PAL standards. These two outputs are also combined to provide a composite video output. All three outputs are available separately at voltages of twice the standard signal levels as required for driving 75 Ω reverse terminated cables. The AD721 also features a bypass mode, in which the RGB inputs may bypass the encoder section of the IC via three gain-of-two amplifiers suitable for driving 75 Ω reverse terminated cables.

The AD720 and AD721 provide a complete, fully calibrated function, requiring only termination resistors, bypass capacitors, a clock input at four times the subcarrier frequency, and a composite sync pulse. There are two control inputs: one input selects the TV standard (NTSC/PAL) and the other (ENCD) powers down most sections of the chip when the encoding function is not in use (AD720) or activates the triple bypass buffer to drive the RGB signals when RGB encoding is not required (AD721). All logical inputs are CMOS compatible. The chip operates from ±5 V supplies.

All required low-pass filters are on chip. After the input signals pass through a precision RGB to YUV encoding matrix, two on-chip low-pass filters limit the bandwidth of the U and V color difference signals to 1.2 MHz prior to quadrature modulation of the color subcarrier; a third low-pass filter at 3.6 MHz (NTSC) or 4.4 MHz (PAL) follows the modulators to limit the harmonic content of the output.

Delays in the U and V chroma filters are matched by an on-chip sampled data delay line in the Y signal path; to prevent aliasing, prefilter at 5 MHz is included ahead of the delay line and a post filter at 5 MHz is added after the delay line to suppress harmonics in the output. These low-pass filters are optimized for minimum pulse overshoot. The overall delay is about 170 ns, which precompensates for delays in the filters used to decode the NTSC or PAL signal in a television receiver. (This precompensation delay is already present in TV broadcasts.)

The AD720 and AD721 are available in a 28-pin plastic leaded chip carrier for the 0°C to +70°C commercial temperature range.

NOTES

[1]Input scaling resistors provide best scaling accuracy when source resistance is 37.5 Ω (75 Ω reverse-terminated input).

[2]Required for driving a 75 Ω double reverse terminated load.

[3]All outputs are measured at a reverse-terminated load; voltages at IC pins are twice those specified here.

[4]This is a predistortion (per FCC specifications) that compensates for the chroma/luma delay in the low-pass filter that separates the luminance and chrominance signals in a television receiver.

[5]CRMA, LUMA, and CMPS outputs are all connected to 75 Ω reverse-terminated loads; full-white signal for entire field.

Specifications shown in **boldface** are tested on all production units at final electrical test. Results from those tests are used to calculate outgoing quality levels. All min and max specifications are guaranteed, although only those shown in **boldface** are tested on all production units.

Specifications subject to change without notice.

ABSOLUTE MAXIMUM RATINGS*

Supply Voltage $\pm V_S$ ..... ±6 V
Internal Power Dissipation ..... 600 mW
Operating Temperature Range ..... 0°C to +70°C
Storage Temperature Range ..... –65°C to +150°C
Lead Temperature, Soldering 60 sec ..... +300°C

NOTE

*Stresses above those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. This is a stress rating only, and functional operation of the device at these or any other conditions above those indicated in the operational section of this specification is not implied. Exposure to absolute maximum rating conditions for extended rating conditions for extended periods may affect device reliability.

Thermal characteristics: 28-pin plastic package: θ_{JA} = 100°C.

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the AD720/AD721 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

THEORY OF OPERATION

Referring to the AD720/AD721 block diagram (Figure 8), the RGB inputs (each 0 mV to 714 mV in NTSC or 0 mV to 700 mV in PAL) are first encoded into luminance and color difference signals. The luminance signal is called the "Y" signal and the color-difference signals are called U and V. The RGB inputs are encoded into the YUV format using the transformation

$$Y = 0.299R + 0.587G + 0.114B$$
$$U = 0.493\ (B-Y)$$
$$V = 0.877\ (R-Y)$$

For NTSC operation, the chroma amplitude is increased by the factor 1.06 prior to summation with the luminance output. The burst signal is inserted into the Y channel in the encoding matrix.

The three outputs of the encoding matrix, now transformed into Y, U, and V components, take two paths. The Y (luminance) signal is passed through a delay line consisting of a prefilter, a sampled-data delay line, and a post filter. The pre- and post-filters prevent aliasing of harmonics back into the baseband video. The overall delay is a nominal –170 ns relative to the chrominance signal, in keeping with broadcast requirements to compensate for delays introduced by the filters in the decoding process.

The U and V components pass through 4-pole modified Bessel low-pass filters with a 1.2 MHz –3 dB frequency to prevent aliasing in the balanced modulators, where they modulate a 3.579 545 000 MHz (NTSC) or 4.433 618 750 MHz (PAL) signal via a pair of balanced modulators driven in quadrature by the color subcarrier.

The AD720/AD721 4FSC input drives a digital divide-by-4 circuit (two flip-flops) to create the quadrature signal. The reference phase 0° is used for the U signal. In the NTSC mode, the V signal is modulated at 90°, but in the PAL mode, the V modulation input alternates between 90° and 270° at half the line rate as required by the PAL standard. The outputs of the balanced modulators are summed and low-pass filtered to remove harmonics.

The filtered output is summed with the luminance signal to create a composite video signal. The separate luminance, chrominance, and composite video signals are amplified by gain-of-two amplifiers for driving 75 Ω reverse-terminated lines. The separate luminance and chrominance outputs together are known as "S-Video."

The digital section of the AD720/AD721 is clocked by the 4FSC input. It measures the width of pulses in the composite sync input to separate vertical, horizontal, and serration pulses and to insert the subcarrier burst only after a valid horizontal sync pulse.

Asserting the ENCD pin to a logical low routes the AD721's RGB inputs through three gain-of-two bypass buffers for driving 75 Ω reverse-terminated lines, bypassing the encoder section of the AD721. The triple bypass amplifier is utilized to overcome the loading effects of a "TV-out" connection on the RGB monitor output. When a video encoder is connected to outputs of a current-out video RAMDAC or VGA controller, the R, G, and B signals to the monitor are loaded-down. This requires the use of a gain block to properly drive the monitor.

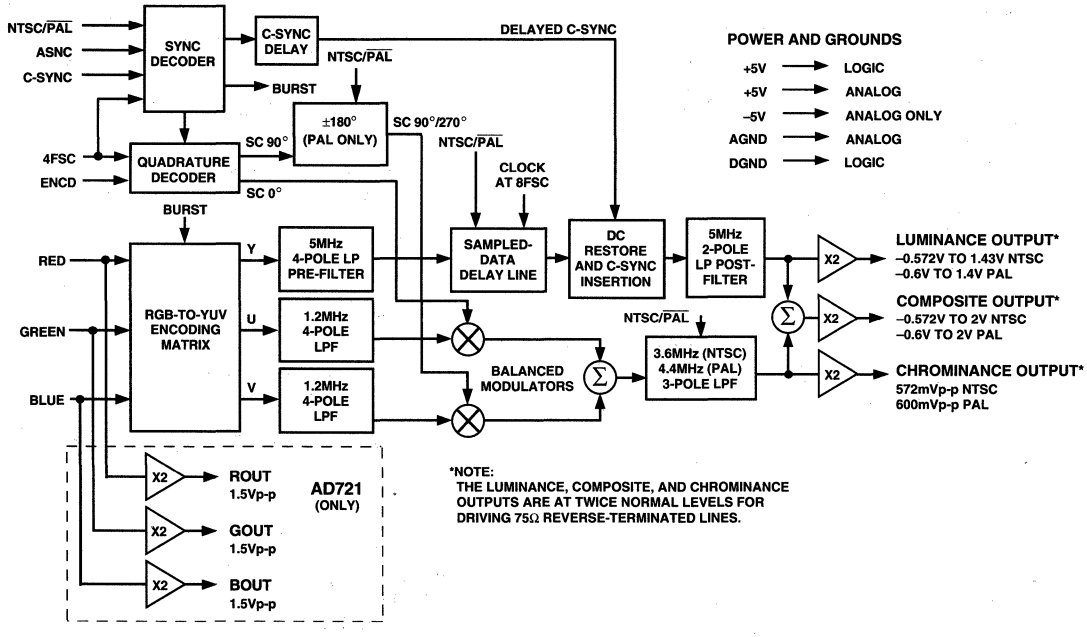

Figure 8. AD720/AD721 Functional Block Diagram

APPLYING THE AD720/AD721

Figure 9 shows the application of the AD720 and Figure 10 shows the application of the AD721. Note that the AD720 and AD721 differ from other analog encoders because they are dc coupled. This means that, for example, the expected RGB inputs are 0 mV to 714 mV in NTSC and 0 mV to 700 mV in PAL. The luminance, chrominance, and composite outputs are also dc coupled. These outputs can drive a 75 Ω reverse-terminated load. Unused outputs should be terminated with 150 Ω resistors.

The RGB data must be supplied to the AD720/AD721 at NTSC or PAL rates, interlaced format. Various VGA chip set vendors support this mode of operation. Most computers supply RGB outputs in noninterlaced format at higher data rates than NTSC and PAL, which means that "outboard" encoders must supply some form of timing conversion before the RGB data reaches the AD720/AD721.

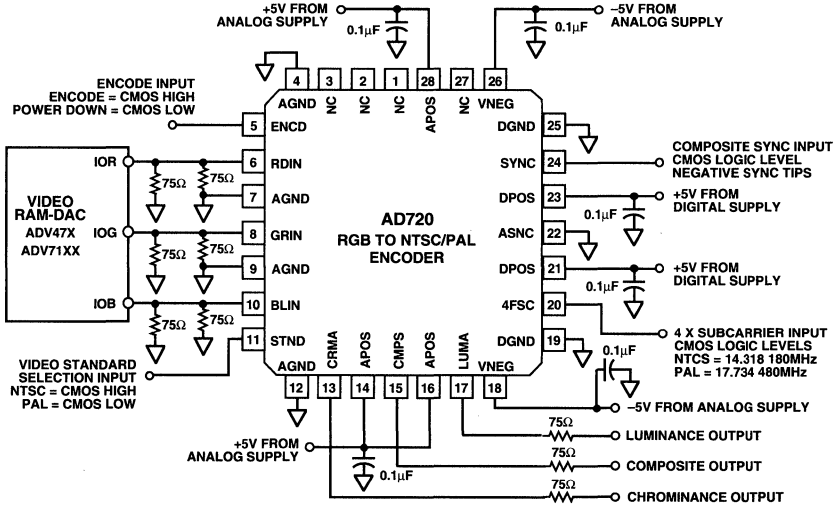

Figure 9. AD720 Application

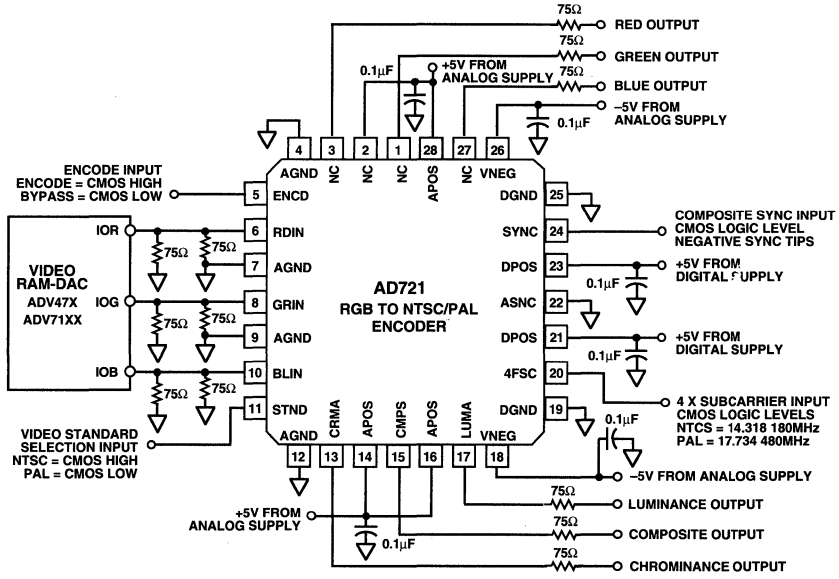

Figure 10. AD721 Application

Note also that the AD720/AD721 does not have internal dc restoration and does not accept sync on green. The composite sync input is a separate, CMOS logical-level input and must be synchronized with the 4FSC input, which serves as the master clock for the AD720/AD721.

The AD720/AD721 does not implement two elements of the PAL and NTSC standards. In NTSC operation, it does not support the 7.5 IRE unit setup (1 IRE unit = 7.14 mV)—this must be added via software using the RGB inputs. Many RAM-DACs, such as the Analog Devices ADV471 and ADV478, offer a logic-selectable setup mode. In PAL operation, the AD720/AD721 does not implement a 25 Hz subcarrier offset.

Decoupling and Grounding

Referring to the pin descriptions, the AD720/AD721 uses multiple analog grounds, digital grounds, digital positive supply inputs, analog positive supply inputs, and analog negative supply inputs in order to maximize isolation between analog and digital signal paths.

The most sensitive input of the AD720/AD721 is the 4FSC pin: any noise on this pin directly affects the subcarrier and causes degradation of the picture. Digital and analog grounds should be kept separate and brought together at a single point.

All power supply pins should be decoupled using 0.1 μF ceramic capacitors located as close to the AD720/AD721 as possible. In addition, ferrite beads may be slipped over the power supply leads to reduce high frequency noise.

If a high speed RAM-DAC is used (e.g., capable of 80 MHz operation with subnanosecond rise times), care must be taken to properly terminate the input printed-circuit-board traces to the AD720/AD721. Otherwise, ringing on these traces may occur and cause degradation of the picture.

APPLICATIONS HINTS

In applying the AD720/AD721, problems may arise due to incorrect input signals. A few common situations follow.

Fade to Black or White—Invalid Horizontal Sync Pulses

Some systems produce sync pulses that are longer or shorter than the NTSC and PAL standards specify. The digital sync separator in the AD720/AD721 ignores horizontal sync pulses that are too long or too short. Figure 11 shows the timing windows for valid NTSC and PAL horizontal sync pulses.

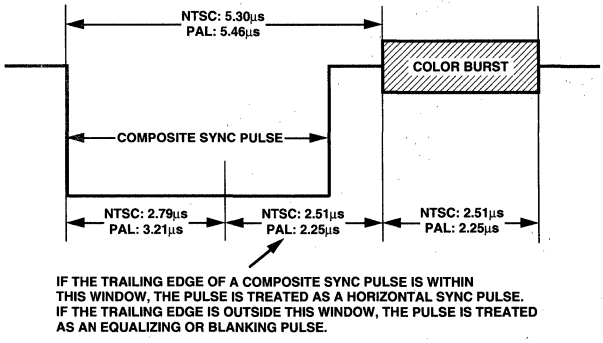

Figure 11. NTSC and PAL Timing for Valid Horizontal Sync Pulses

When the horizontal sync pulses are too long or too short, a dc offset voltage (due to charge storage) increases on the output of the sampled data delay line's auto-zero amplifier. Normally, this offset voltage is removed at the beginning of every line, as signified by the horizontal sync pulse. Without the horizontal sync pulse, the dc offset on the auto-zero amplifier increases over time (usually about three to five minutes) until it overrides the luminance information. The end result is a slow fade to black or white.

Color Flickering—Asynchronous Operation

The AD720/AD721 requires that its 4FSC and composite sync signals be synchronized. In most systems, when the two signals are synchronized, the composite sync signal is generated using a 4FSC signal as the reference. After every four frames, the AD720/AD721 resets the phase quadrature generator. When the CSYNC and 4FSC are synchronized, this reset is transparent to the system because the reference phase does not change. When the CSYNC and 4FSC are not synchronized, the difference between the reference phase and its new value upon reset causes an instantaneous color shift, which appears as a flickering in the color.

Adding NTSC Setup

The easiest way to add the 7.5 IRE unit[1] setup is to use a ADV471/478 or ADV477/475 or ADV473 type RAM-DAC, which have a logic-selectable setup (called "pedestal" on some data sheets and "setup" on others).

Color Fidelity

A source impedance other than 37.5 Ω (75 Ω‖75 Ω—a reverse-terminated 75 Ω input) can cause errors in the YUV encoding matrix, which is basically resistive and depends on the correct source impedance for accuracy. Figures 9 and 10 show the correct interface between a RAM-DAC and the AD720 and AD721 respectively, using 75 Ω reverse-terminated connections.

NOTE
[1]IRE unit = 7.14 mV.

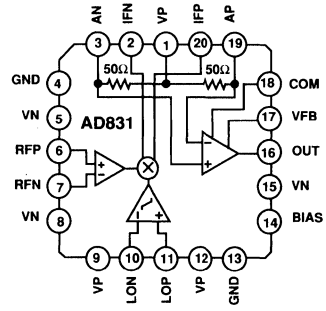
User-Programmable Power Consumption

APPLICATIONS

High Performance RF/IF Mixer
Direct to Baseband Conversion
Image-Reject Mixers
I/Q Modulators and Demodulators

FUNCTIONAL BLOCK DIAGRAM



PRODUCT DESCRIPTION

The AD831 is a low distortion, wide dynamic range, monolithic mixer for use in such applications as RF to IF down conversion in HF and VHF receivers, the second mixer in DMR base stations, direct-to-baseband conversion, quadrature modulation and demodulation, and doppler-shift detection in ultrasound imaging applications. The mixer includes an LO driver and a low-noise output amplifier and provides both user-programmable power consumption and 3rd-order intercept point.

The AD831 provides a +24 dBm third-order intercept point for –10 dBm LO power, thus improving system performance and reducing system cost compared to passive mixers, by eliminating the need for a high power LO driver and its attendant shielding and isolation problems.

The RF, IF, and LO ports may be dc or ac coupled when the mixer is operating from ±5 V supplies or ac coupled when operating from a single supply of 9 V minimum. The mixer operates with RF and LO inputs as high as 500 MHz.

The mixer's IF output is available as either a differential current output or a single-ended voltage output. The differential output is from a pair of open collectors and may be ac coupled via a transformer or capacitor to provide a 250 MHz output bandwidth. In down-conversion applications, a single capacitor connected across these outputs implements a low-pass filter to reduce harmonics directly at the mixer core, simplifying output filtering. When building a quadrature-amplitude modulator or image reject mixer, the differential current outputs of two AD831s may be summed by connecting them together.

An integral low noise amplifier provides a single-ended voltage output and can drive such low impedance loads as filters, 50 Ω amplifier inputs, and A/D converters. Its small signal bandwidth exceeds 200 MHz. A single resistor connected between pins OUT and FB sets its gain. The amplifier's low dc offset allows its use in such direct-coupled applications as direct-to-baseband conversion and quadrature-amplitude demodulation.

The mixer's SSB noise figure is 12 dB using its output amplifier and optimum source impedance. Unlike passive mixers, the AD831 has no insertion loss and does not require an external diplexer or passive termination.

A programmable-bias feature allows the user to reduce power consumption, with a reduction in the 1 dB compression point and third-order intercept. This permits a tradeoff between dynamic range and power consumption. For example, the AD831 may be used as a second mixer in cellular and two-way radio base stations at reduced power while still providing a substantial performance improvement over passive solutions.

PRODUCT HIGHLIGHTS

1. –10 dBm LO Drive for a +24 dBm Output Referred Third Order Intercept Point
2. Single-Ended Voltage Output
3. High Port-to-Port Isolation
4. No Insertion Loss
5. Single or Dual Supply Operation

THEORY OF OPERATION

The AD831 consists of a mixer core, a limiting amplifier, a low noise output amplifier, and a bias circuit (Figure 12).

The mixer's RF input is converted into differential currents by a highly linear, Class A voltage-to-current converter, formed by transistors Q1, Q2 and resistors R1, R2. The resulting currents drive the differential pairs Q3, Q4 and Q5, Q6. The LO input is through a high gain, low noise limiting amplifier that converts the –10 dBm LO input into a square wave. This square wave drives the differential pairs Q3, Q4 and Q5, Q6 and produces a high level output at IFP and IFN—consisting of the sum and difference frequencies of the RF and LO inputs—and a series of lower level outputs caused by odd harmonics of the LO frequency mixing with the RF input.

An on-chip network supplies the bias current to the RF and LO inputs when these are ac coupled; this network is disabled when the AD831 is dc coupled.

When the integral output amplifier is used, pins IFN and IFP are connected directly to pins AFN and AFP; the on-chip load resistors convert the output current into a voltage that drives the output amplifier. The ratio of these load resistors to resistors R1, R2 provides nominal unity gain (0 dB) from RF to IF. The expression for the gain, in decibels, is

$$G_{dB} = 20 \log_{10}\left(\frac{4}{\pi}\right)\left(\frac{1}{2}\right)\left(\frac{\pi}{2}\right) \qquad \text{Equation 1}$$

where

$\frac{4}{\pi}$ is the amplitude of the fundamental component of a square wave

$\frac{1}{2}$ is the conversion loss

$\frac{\pi}{2}$ is the small signal dc gain of the AD831 when the LO input is driven fully positive or negative.

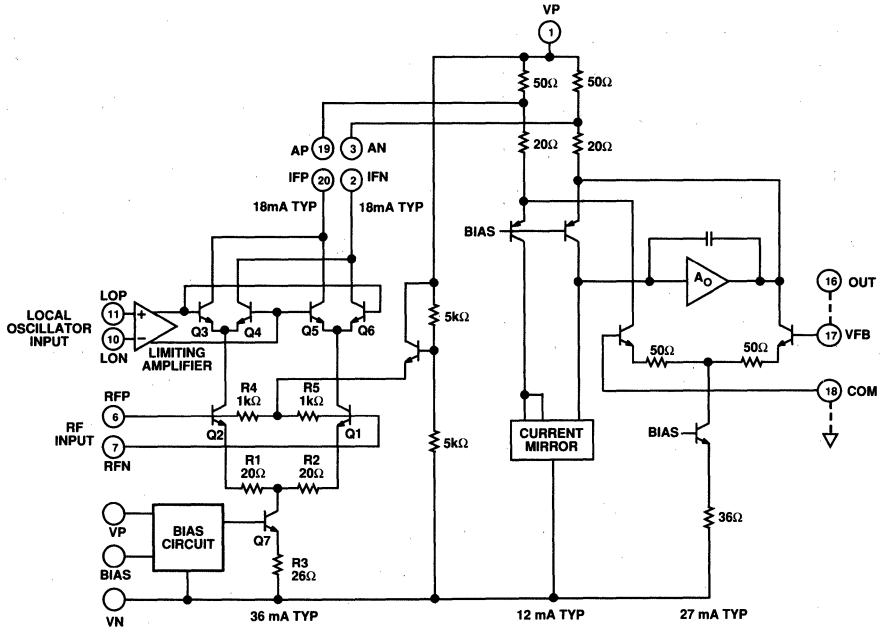

Figure 12. AD831 Simplified Schematic Diagram

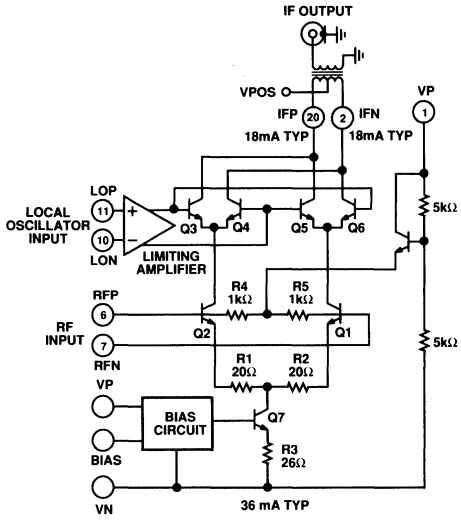

Figure 13. Connections for Transformer Coupling to the IF Output

The mixer has two open-collector outputs (differential currents) at pins IFN and IFP. These currents may be used to provide nominal unity RF-to-IF gain by connecting a center-tapped transformer (1:1 turns ratio) to pins IFN and IFP as shown in Figure 13.

Programming the Bias Current

Because the AD831's RF port is a Class-A circuit, the maximum RF input is proportional to the bias current. This bias current may be reduced by connecting a resistor from the BIAS pin to the positive supply (Figure 14). For normal operation, the BIAS pin is left unconnected. For lowest power consumption, the BIAS pin is connected directly to the positive supply The range of adjustment is 100 mA for normal operation to 45 mA total current at minimum power consumption.

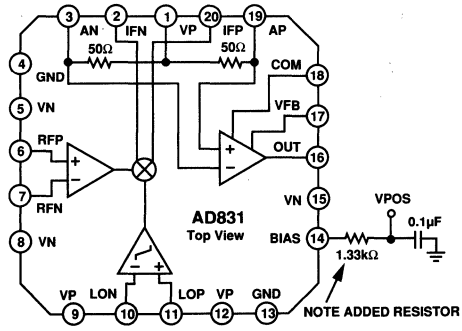

Figure 14. Programming the Quiescent Current

Low-Pass Filtering

A simple low-pass filter may be added between the mixer and the output amplifier by shunting the internal resistive loads (an equivalent resistance of about 14 Ω with a tolerance of 20%) with external capacitors; these attenuate the sum component in a down-conversion application (Figure 15). The corner frequency of this one-pole low-pass filter ($f = (2\pi RC_F)^{-1}$) should be placed about an octave above the difference frequency IF. Thus, for a 70 MHz IF, a –3 dB frequency of 140 MHz might be chosen, using $C_F = (2 \times \pi \times 14\ \Omega \times 140\ \text{MHz})^{-1} \approx 82$ pF, the nearest standard value.

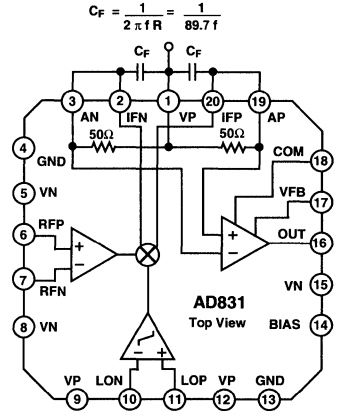

Figure 15. Low-Pass Filtering Using External Capacitors

Using the Output Amplifier

The AD831's output amplifier converts the mixer core's differential current output into a single-ended voltage and provides an output as high as ±1 V peak into a 50 Ω load (+10 dBm). For unity gain operation (Figure 16), the inputs AN and AP connect to the open-collector outputs of the mixer's core and OUT connects to VFB.

For gains other than unity, the amplifier's output at OUT is connected via an attenuator network to VFB; this determines the overall gain. Using resistors R1 and R2 (Figure 17), the gain setting expression is

$$G_{dB} = 20 \log_{10}\left(\frac{R1 + R2}{R2}\right) \qquad \text{Equation 2}$$

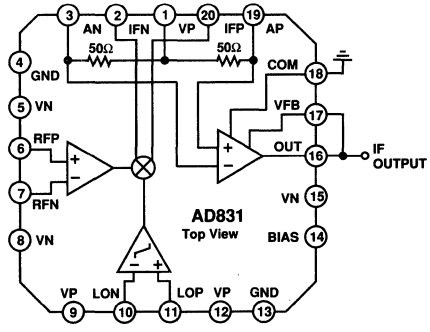

Figure 16. Output Amplifier Connected for Unity Gain Operation

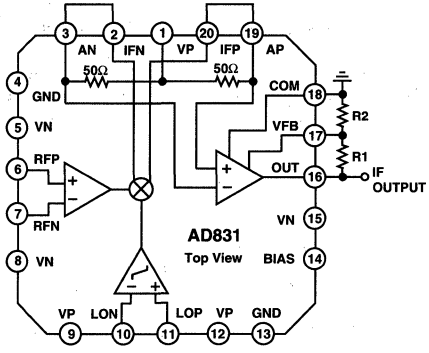

Figure 17. Output Amplifier Feedback Connections for Increasing Gain

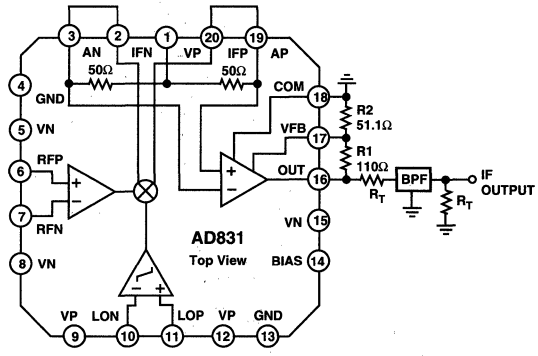

Figure 18. Connections for Driving a Doubly-Terminated Bandpass Filter

Driving Filters

The output amplifier can be used for driving reverse-terminated loads. When driving an IF bandpass *filter* (BPF), for example, proper attention must be paid to providing the optimal source and load terminations so as to achieve the specified filter response. The AD831's wideband highly linear output amplifier affords an opportunity to increase the RF-to-IF gain to compensate for a filter's insertion and termination losses.

Figure 18 indicates how the output amplifier's low impedance (voltage source) output can drive a doubly-terminated bandpass filter. The typical 10 dB of loss (4 dB of insertion loss and 6 dB due to the reverse-termination) be made up by the inclusion of a feedback network that increases the gain of the amplifier by 10 dB (×3.162). When constructing a feedback circuit, the signal path between OUT and VFB should be as short as possible.

Higher gains can be achieved, using different resistor ratios, but with concomitant reduction in the bandwidth of this amplifier (Figure 19). Note also that the Johnson noise of these gain-setting resistors, as well as that of the BPF terminating resistors, is ultimately reflected back to the mixer's input; thus they should be as small as possible, consistent with the permissible loading on the amplifier's output.

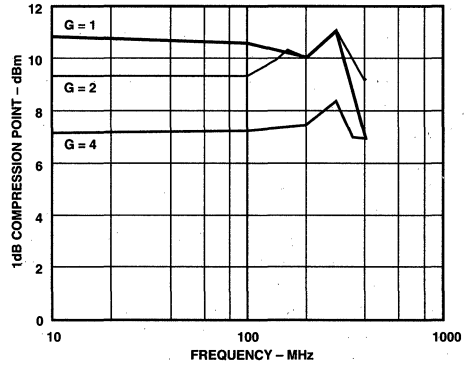

Figure 19. Output Amplifier 1 dB Compression Point for Gains of 1, 2, and 4 (Gains of 0 dB, 6 dB, and 12 dB, respectively)

APPLICATIONS

Careful component selection, circuit layout, power supply decoupling, and shielding are needed to minimize the AD831's susceptibility to interference from radio and TV stations, etc. In bench evaluation, we recommend placing all of the components in a shielded box and using feedthrough decoupling networks for the supply voltage.

Circuit layout and construction are also critical, since stray capacitances and lead inductances can form resonant circuits and are a potential source of circuit peaking, oscillation, or both.

Dual-Supply Operation

Figure 20 shows the connections for dual supply operation. Supplies may be as low as ±4.5 V but should be no higher than ±5.5 V due to power dissipation.

The RF input to the AD831 is shown connected single-ended to pin RFP with 51.1 Ω input termination resistor with an assumed source impedance of 50 Ω. The 82 pF capacitors (C_F) connected from IFN and IFP to VP provide a low-pass filter with a cutoff frequency of approximately 140 MHz in down-conversion applications (see the Theory of Operation section of this data sheet for more details). The LO input is connected single-ended because the limiting amplifier provides a symmetric drive to the mixer. To minimize intermodulation distortion, connect pins OUT and VFB by the shortest possible path. The connections shown are for unity-gain operation.

At LO frequencies less than 100 MHz, the AD831's LO power may be as low as –20 dBm for satisfactory operation. Above 100 MHz, the specified LO power of –10 dBm must be used.

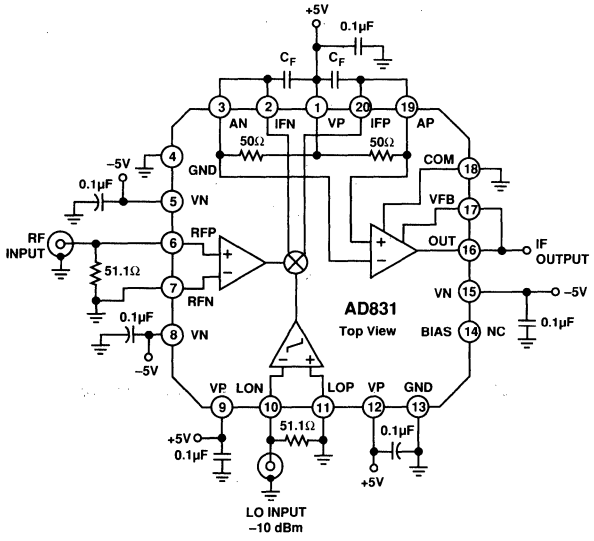

Figure 20. Connections for ±5 V Dual-Supply Operation

21

Single Supply Operation

Figure 21 is similar to the dual supply circuit in Figure 19. Supplies may be as low as 9 V but should not be higher than 11 V due to power dissipation. As in Figure 19, both the RF and LO ports are driven single-ended and terminated.

In single supply operation, the COM terminal is the "ground" reference for the output amplifier and must be biased to 1/2 the supply voltage, which is done by resistors R1 and R2. The OUT pin must be ac-coupled to the load.

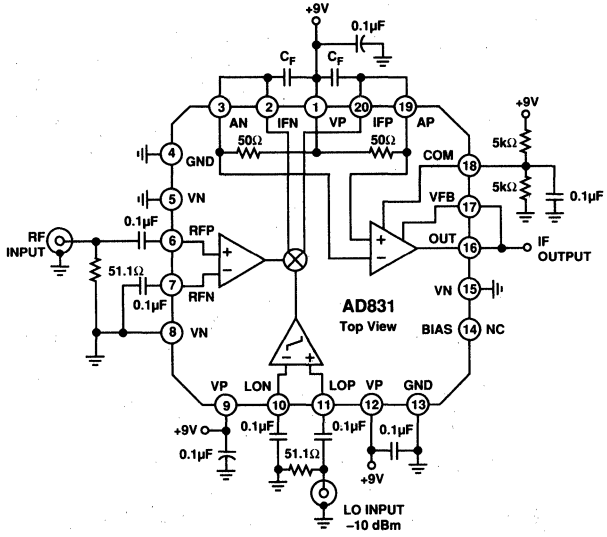

Figure 21. Connections for +9 V Single-Supply Operation

Connections Quadrature Demodulation

Two AD831 mixers may have their RF inputs connected in parallel and have their LO inputs driven in phase quadrature (Figure 22) to provide demodulated in-phase (I) and quadrature (Q) outputs. The mixers' inputs may be connected in parallel and a single termination resistor used if the mixers are located in close proximity on the PC board.

CMOS DDS Modulator

AD7008

FEATURES
Single +5 V Supply
32-Bit Phase Accumulator
On-Chip COSINE and SINE Look-Up Tables
On-Chip 10-Bit DAC
Frequency, Phase and Amplitude Modulation
Parallel and Serial Loading
Software and Hardware Power Down Options
20 MHz and 50 MHz Speed Grades
44-Pin PLCC

APPLICATIONS
Frequency Synthesizers
Frequency, Phase or Amplitude Modulators
DDS Tuning
Digital Demodulation

GENERAL DESCRIPTION

The AD7008 direct digital synthesis chip is a numerically controlled oscillator employing a 32-bit phase accumulator, sine and cosine look-up tables and a 10-bit D/A converter integrated on a single CMOS chip. Modulation capabilities are provided for phase modulation, frequency modulation, and both in-phase and quadrature amplitude modulation suitable for SSB generation.

Clock rates up to 20 MHz and 50 MHz are supported. Frequency accuracy can be controlled to one part in 4 billion. Modulation may be effected by loading registers either through the parallel microprocessor interface or the serial interface. A frequency-select pin permits selection between two frequencies on a per cycle basis.

The serial and parallel interfaces may be operated independently and asynchronously from the DDS clock; the transfer control signals are internally synchronized to prevent metastability problems. The synchronizer can be bypassed to reduce the transfer latency in the event that the microprocessor clock is synchronous with the DDS clock.

A power-down pin allows external control of a power-down mode (also accessible through the microprocessor interface). The AD7008 is available in 44-pin PLCC.

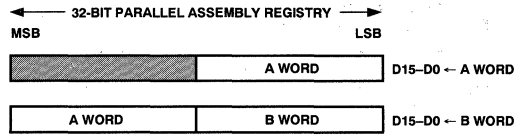

Figure 5. 16-Bit Parallel Port Loading Sequence

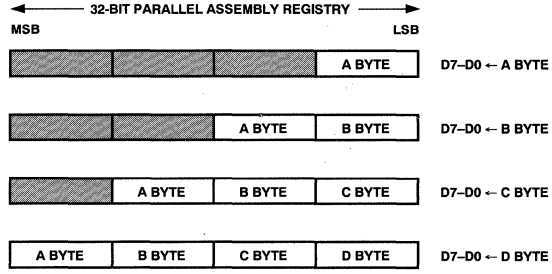

Figure 6. 8-Bit Parallel Port Loading Sequence

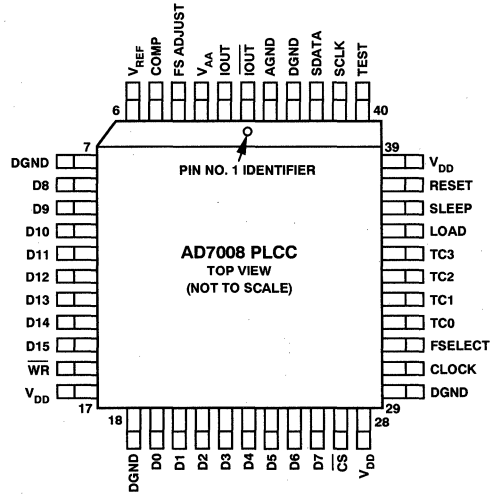
CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the AD7008 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

PIN CONFIGURATION
PLCC



PIN DESCRIPTION

Mnemonic	Function
POWER SUPPLY	
V_{AA}	Positive power supply for the analog section. A 0.1 μF decoupling capacitor should be connected between V_{AA} and AGND. This is +5 V ± 5 %.
AGND	Analog Ground.
V_{DD}	Positive power supply for the digital section. A 0.1 μF decoupling capacitor should be connected between V_{DD} and DGND. This is +5 V ± 5%. Both V_{AA} and V_{DD} should be externally tied together.
DGND	Digital Ground; both grounds should be externally tied together.
ANALOG SIGNAL AND REFERENCE	
IOUT, $\overline{IOUT}$	Current Output. This is a high impedance current source. A load resistor should be connected between IOUT and AGND. $\overline{IOUT}$ should be either tied directly to AGND or through an external load resistor to AGND.
FS ADJUST	Full-Scale Adjust Control. A resistor (R_{SET}) is connected between this pin and AGND. This determines the magnitude of the full-scale DAC current. The relationship between R_{SET} and the full-scale current is as follows: $IOUT_{FULL\text{-}SCALE}\ (mA) = 6233 \times V_{REF}\ (V)/R_{SET}\ (\Omega)$
V_{REF}	Voltage Reference Input. A 0.1 μF decoupling ceramic capacitor should be connected V_{REF} and V_{AA}. There is an internal 1.27 voltage reference which can over driven by an external reference if required.
COMP	Compensation pin. This is a compensation pin for the internal reference amplifier. A 0.1 μF decoupling ceramic capacitor should be connected between COMP and V_{AA}.
DIGITAL INTERFACE AND CONTROL	
CLOCK	Digital Clock Input. DDS output frequencies are expressed as a binary fraction of the frequency of this clock. Hence, the output frequency accuracy and phase noise is determined by this clock.
FSELECT	Frequency Select Input. FSELECT controls which frequency register, FREQ0 or FREQ1, is used in the phase accumulator. Frequency selection can be done on a cycle-per-cycle basis.
LOAD	Register load, active high digital Input. This pin, in conjunction with TC3–TC0, control loading of internal registers from either the parallel or serial assembly registers.
TC3–TC0	Transfer Control address bus, digital inputs. This address determines the source and destination registers that are used during a transfer. The source register can either be the parallel assembly register or the serial assembly register. The destination register can be any of the following: COMMAND REG, FREQ0 REG, FREQ1 REG, PHASE REG or IQMOD REG. TC3-TC0 should be valid prior to LOAD rising and should not change until LOAD falls.
$\overline{CS}$	Chip Select, active low digital input. This input in conjunction with $\overline{WR}$ is used when writing to the parallel assembly register.
$\overline{WR}$	Write, active low digital input. This input in conjunction with $\overline{CS}$ is used when writing to the parallel assembly register.
D7–D0	Data bus, digital inputs. This represent the low byte of the 16-bit data input port used to write to the 32-bit parallel assembly register. The databus can configured for either a 8-bit or 16-bit MPU/DSP ports.
D15–D8	Data Bus, Digital Inputs. This represent the high byte of the 16-bit data input port used to write to the 32-bit parallel assembly register. The databus can configured for either a 8-bit or 16-bit MPU/DSP ports. When the databus is configured for 8-bit operation, D8–D15 should be tied to DGND.
SCLK	Serial Clock, digital input. SCLK is used, in conjunction with SDATA, to clock data into the 32-bit serial assembly register.
SDATA	Serial Data, digital input. Serial data is clocked on the rising edge of SCLK, Most Significant Bit (MSB) first.
SLEEP	Low power sleep control, active high digital input. SLEEP puts the AD7008 into a low power sleep mode. Internal clocks are disable while also turning off the DAC current sources. A SLEEP bit is also provided in the COMMAND REG to put the AD7008 into a low power sleep mode.
RESET	Register Reset, active high digital input. RESET clears the COMMAND REG and all the modulation registers to zero.
TEST	Test Mode. This used for factory test only and should be left as a No Connect.

CIRCUIT DESCRIPTION

In contrast to previous direct digital synthesizer devices, the AD7008 provides an exciting new level of integration for the RF/Communications system designer. The AD7008 combines the numerical controlled oscillator (NCO), SIN/COSINE look-up tables, frequency, phase and IQ modulators, and a digital-to-analog converter on a single integrated circuit.

The internal circuitry of the AD7008 consists of four main sections. These are

Numerical Controlled Oscillator (NCO) + Phase Modulator
SIN and COSINE look up tables
In Phase and Quadrature Modulators
Digital-to-Analog Converter

Numerical Controlled Oscillator + Phase Modulator

This consists of two frequency select registers, a phase accumulator and a phase offset register. The main component of the NCO is a 32-bit phase accumulator which accumulates a phase step on every clock cycle. The value of the phase step determines how many clocks cycles are required for the phase accumulator to count 2π radians (i.e., one cycle of the output frequency). The output frequency, f_{OUT}, is given by:

$$f_{OUT} = \frac{Phase\ Step}{2\pi} f_{CLOCK} = \frac{\Delta\ Phase}{2^{32}} f_{CLOCK}$$

$$0 \leq \Delta\ Phase \leq 2^{32} - 1$$

The input to the phase accumulator (i.e., the phase step) can be selected either from the FREQ0 Register or FREQ1 Register and this is controlled by the FSELECT pin. This allows binary frequency shift keying to be easily implemented. The two FSK frequencies can be loaded into FREQ0 and FREQ1 and selected using the FSELECT pin. NCOs inherently generate continuous phase signals, thus avoiding any output discontinuity when switching between frequencies. More complex frequency modulation schemes, such as GMSK, can be implemented by updating the contents of these registers.

Following the NCO, a phase offset can be added to perform phase modulation using the 12-bit PHASE Register. The contents of this register are added to the most significant bits of the NCO.

Sin and Cosine Look-Up Tables (LUT)

The output of the phase accumulator is converted to an amplitude signal by means of an Sine/Cosine ROM LUT. Although the NCO contains a 32-bit phase accumulator, the output of the NCO is truncated to 12-bits. Using the full resolution of the phase accumulator is both impractical and unnecessary as this would require a look-up table of 2^{32} entries.

It is necessary only to have sufficient phase resolution in the LUTs such that the dc error of the output waveform is dominated by the quantization error in the DAC. This requires the look-up tables to have two more bits of phase resolution than the 10-bit DAC.

In Phase and Quadrature Modulators

Two 10-bit amplitude multipliers are provided allowing the easy implementation of either Quadrature Amplitude Modulation (QAM) or Amplitude Modulation (AM). The 20-bit IQMOD Register is used to control the amplitude of the I (cosine) and Q (sine) signals. IQMOD[9–0] controls the I amplitude and IQMOD[19–10] controls the Q amplitude.

The user should ensure that when summing the I and Q signals the result should not exceed 10-bits, as there is no internal clipping logic to prevent overflow.

When amplitude modulation is not required, the IQ multipliers can be bypassed (CR2 = 0). The sine output is directly sent to the 10-bit DAC.

Digital-to-Analog Converter

The AD7008 include a high impedance current source 10-bit DAC, capable of driving wide range of loads at different speeds. Full-scale output current can be adjusted, for optimum power and external load requirements, through the use of a single external resistor (R_{SET}).

The DAC can be configured for single or differential ended operation. $\overline{I_{OUT}}$ can be either tied directly to AGND for single ended operation or through external load resistor.

MPU Interface

The chip contains two 32-bit assembly registers, one for parallel bus data, and one for serial input data. Each of the modulation registers can be loaded from either assembly register under control of the LOAD pin and the Transfer-Control (TC) pins (See Table I). The Command register can only be loaded from the parallel assembly register.

Table I. Source and Destination Registers

TC3	TC2	TC1	TC0	LOAD	Source Register	Destination Register
X	X	X	X	0	N/A	N/A
0	0	X	X	1	Parallel	COMMAND
1	0	0	0	1	Parallel	FREQ0
1	0	0	1	1	Parallel	FREQ1
1	0	1	0	1	Parallel	PHASE
1	0	1	1	1	Parallel	IQMOD
1	1	0	0	1	Serial	FREQ0
1	1	0	1	1	Serial	FREQ1
1	1	1	0	1	Serial	PHASE
1	1	1	1	1	Serial	IQMOD

Table II. AD7008 Control Registers

Register	Size	Reset State	Description
COMMAND REG	4 Bits CR3–CR0	All Zeros	Command Register. This is written to using the parallel assembly register.
FREQ0 REG	32 Bits DB31–DB0	All Zeros	Frequency Select Register 0. This defines the output frequency, when FSELECT = 0, as a fraction of the CLOCK frequency.
FREQ1 REG	32 Bits DB31–DB0	All Zeros	Frequency Select Register 1. This defines the output frequency, when FSELECT = 1, as a fraction of the CLOCK frequency.
PHASE REG	12 Bits DB11–DB0	All Zeros	Phase Offset Register. The contents of this register is added to the output of the phase accumulator.
IQMOD REG	20 Bits DB19–DB0	All Zeros	I and Q Amplitude Modulation Register. This defines the amplitude of the I and Q signals as 10-bit two complement binary fractions. DB[19:10] is multiplied by the Quadrature (sine component and DB[9:0] is multiplied by the In-Phase (cosine) component.

Table III. Command Register Bits

CR0	=0	Eight-Bit Databus. Pins D15–D8 are ignored and the parallel assembly register shifts eight places left on each write. Hence four successive writes are required to load the 32-bit parallel assembly register, Figure 6.
	=1	Sixteen-Bit Databus. The parallel assembly register shifts 16 places left on each write. Hence two successive writes are required to load the 32-bit parallel assembly register, Figure 5.
CR1	=0	Normal Operation.
	=1	Low Power Sleep Mode. Internal Clocks and the DAC current sources are turn off.
CR2	=0	Amplitude Modulation Bypass. The output of the sine LUT is directly sent to the DAC.
	=1	Amplitude Modulation Enable. IQ modulation is enabled allowing AM or QAM to be performed.
CR3	=0	Synchronizer Logic Enabled. The FSELECT, LOAD and TC3–TC0 signals are passed through a 4-stage pipeline to synchronize them with the CLOCK frequency, avoiding metastability problems.
	=1	Synchronizer Logic Disabled. The FSELECT, LOAD and TC3–TC0 signals bypass the synchronization logic. This allows for faster response to the control signals.

TC3–TC0 should be set up and stable before LOAD rises, and should not change until after LOAD falls.

The microprocessor asserts both $\overline{WR}$ and $\overline{CS}$ to load the parallel assembly register. At the end of each write, the parallel assembly register is shifted left by 8 or 16 bits (depending on CR0), and the new data is loaded into the low bits. Hence, two 16-bit writes or four 8-bit writes are used to load the parallel assembly register. When loading parallel data destined for the phase or IQ registers, it is only necessary to write as much data as will be used by that register. For instance, the Command Register requires only one write to the parallel assembly register.

Serial data is input to the chip on the rising edge of SCLK, most significant bit first. The data in the assembly registers can be transferred to the modulation registers by means of the transfer control pins.

APPLICATIONS

The AD7008 can be used in a wide range of communication applications ranging from digital mobile radio, to frequency agile Wireless Local Area Networks (WANs), to SSB telephony.

For digital mobile radio applications the chip provides direct synthesis and phase modulation capabilities to 20 MHz in a single low power, low cost part.

For WANs a wide range of modulation capabilities allow a system developer to optimize modulation bandwidth and noise immunity.

In the area of SSB telephony (military, commercial and amateur), the chip provides the first single chip implementation of a phasing type SSB generator. Combined with a single chip DSP (ADSP-2101) implementing the speech input and Hilbert transform, the AD7008 forms a two-chip direct SSB generation capability to over 20 MHz.

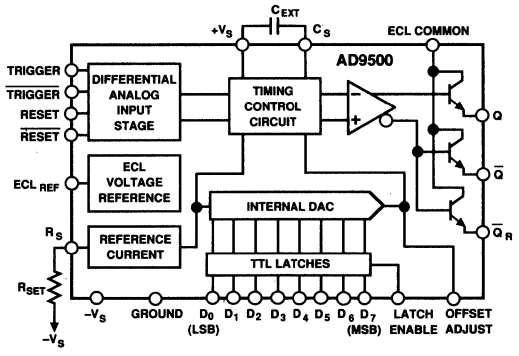
Digitally Programmable Delay Generator

AD9500

FEATURES
10ps Delay Resolution
2.5ns to 10μs Full-Scale Range
Fully Differential Inputs
Separate Trigger and Reset Inputs
Low Power Dissipation – 310mW
MIL-STD-883 Compliant Versions Available

APPLICATIONS
ATE
Pulse Deskewing
Arbitrary Waveform Generators
High-Stability Timing Source
Multiple Phase Clock Generators

FUNCTIONAL BLOCK DIAGRAM



GENERAL DESCRIPTION

The AD9500 is a digitally programmable delay generator, which provides programmed delays, selected through an 8-bit digital code, in resolutions as small as 10ps. The AD9500 is constructed in a high-performance bipolar process, designed to provide high-speed operation for both digital and analog circuits.

The AD9500 employs differential TRIGGER and RESET inputs which are designed primarily for ECL signal levels but function with analog and TTL input levels. An on-board ECL reference midpoint allows both of the inputs to be driven by either single ended or differential ECL circuits. The AD9500 output is a complementary ECL stage, which also provides a parallel $\overline{Q_R}$ output circuit to facilitate reset timing implementations.

The digital control data is passed to the AD9500 through a transparent latch controlled by the LATCH ENABLE signal. In the transparent mode, the internal DAC of the AD9500 will attempt to follow changes at the inputs. The LATCH ENABLE is otherwise used to strobe the digital data into the AD9500 latches.

The AD9500 is available as an industrial temperature range device, −25°C to +85°C, and as an extended temperature range device, −55°C to +125°C. Both grades are packaged in a 24-pin ceramic "Skinny" DIP (0.3" package width), as well as 28-pin surface mount packages. The AD9500 is available in versions compliant with MIL-STD-883. Refer to the Analog Devices Military Products Databook or current AD9500/883B data sheet for detailed specifications.

NOTES

[1]Absolute maximum ratings are limiting values, to be applied individually, and beyond which serviceability of the circuit may be impaired. Functional operability under any of these conditions is not necessarily implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.

[2]Typical thermal impedance

24-Pin Ceramic $\theta_{JA} = 56°C/W$; $\theta_{JC} = 16°C/W$
28-Pin PLCC (Plastic) $\theta_{JA} = 60°C/W$; $\theta_{JC} = 22°C/W$
28-Pin Ceramic LCC $\theta_{JA} = 69°C/W$; $\theta_{JC} = 25°C/W$

[3]$R_{SET} = 10k\Omega$ (Full-scale delay = 100ns).

[4]The digital data inputs must remain stable for the specified time prior to the LATCH ENABLE signal.

[5]The digital data inputs must remain stable for the specified time after the LATCH ENABLE signal.

[6]The TRIGGER and RESET inputs are differential and must be driven relative to one another. Both of these inputs are ECL compatible, but can also be used with TTL logic families in a limited fashion.

[7]Outputs terminated through 50Ω resistors to −2.0V.

[8]Program Delay = 0.0ps (Digital Data = 00_H). In Operation, any programmed delays are in addition to the Minimum Propagation Delay.

[9]Change in total delay through AD9500, exclusive of changes in minimum-propagation delay t_{PD}.

[10]Measured from the 50% transition point of the reset signal input, to the 50% transition point of the resetting output.

[11]Minimum time from falling edge of RESET to triggering input, to insure a valid output event.

[12]Minimum time from triggering event to rising edge of RESET, to insure a valid output event.

[13]Measured from the LATCH ENABLE input to the point when the AD9500 becomes 8-bit accurate again, after a full-scale change in the programmed delay.

[14]Standard 10K and 10KH ECL families operate with a 1.1mV/°C drift by design.

[15]Supply voltages should remain stable within ±5% for normal operation.

[16]Measured at ±5% of $-V_S$ and $+V_S$.

Specifications subject to change without notice.

EXPLANATION OF TEST LEVELS

Test Level

I – 100% production tested.
II – 100% production tested at +25°C, and sample tested at specified temperatures.
III – Periodically sample tested.
IV – Parameter is guaranteed by design and characterization testing.
V – Parameter is a typical value only.
VI – All devices are 100% production tested at +25°C. 100% production tested at temperature extremes for extended temperature devices; sample tested at temperature extremes for commercial/industrial devices.

FUNCTIONAL DESCRIPTION

PIN NAME	DESCRIPTION
D_4–D_6	– One of eight digital inputs used to set the programmed delay.
D_7 (MSB)	– One of eight digital inputs used to set the programmed delay. D_7 (MSB) is the most significant bit of the digital input word.
ECL_{REF}	– ECL midpoint reference, nominally −1.3V. Use of the ECL_{REF}, allows either of the TRIGGER or the RESET inputs to be configured for single-ended ECL inputs.
OFFSET ADJUST	– The OFFSET ADJUST is used to adjust the minimum propagation delay (t_{PD}), by pulling or pushing a small current out of or into the pin.
C_S	– C_S allows the full-scale range to be extended by using an external timing capacitor. The value of C_{EXT}, connected between C_S and $+V_S$, may range from no external capacitance to 0.1μF+. See R_S ($C_{INTERNAL}$ = 10pF).
$+V_S$	– Positive supply terminal, nominally +5.0V.
TRIGGER	– Noninverted input of the edge-sensitive differential trigger input stage. The output at Q will be delayed by the programmed delay, after the triggering event. The programmed delay is set by the digital input word. The TRIGGER input must be driven in conjunction with the $\overline{\text{TRIGGER}}$ input.
$\overline{\text{TRIGGER}}$	– Inverted input of the edge-sensitive differential trigger input stage. The output at Q will be delayed by the programmed delay, after the triggering event. The programmed delay is set by the digital input word. The $\overline{\text{TRIGGER}}$ input must be driven in conjunction with the TRIGGER input.
$\overline{\text{RESET}}$	– Inverted input of the level-sensitive differential reset input stage. The output at Q will be reset after a signal is received at the reset inputs. In the "minimum configuration," the minimum output pulse width will be equal to the "reset propagation delay," t_{RD}. The RESET input must be driven in conjunction with the $\overline{\text{RESET}}$ input.
RESET	– Noninverted input of the level-sensitive differential reset input stage. The output at Q will be reset after a signal is received at the reset inputs. In the "minimum configuration," the minimum output pulse width will be equal to the "reset propagation delay," t_{RD}. The $\overline{\text{RESET}}$ input must be driven in conjunction with the RESET input.
Q	– One of two complementary ECL outputs. A "triggering" event at the inputs will produce a logic HIGH on the Q output. A "resetting" event at the inputs will produce a logic LOW on the Q output
$\overline{Q}$	– One of two complementary ECL outputs. A "triggering" event at the inputs will produce a logic LOW on the $\overline{Q}$ output. A "resetting" event at the inputs will produce a logic HIGH on the $\overline{Q}$ output.
$\overline{Q_R}$	– $\overline{Q_R}$ output is parallel to the $\overline{Q}$ output. The $\overline{Q_R}$ output is typically used to drive delaying circuits for extending output pulse widths. A "triggering" event at the inputs will produce a logic LOW on the $\overline{Q_R}$ output. A "resetting" event at the inputs will produce a logic HIGH on the $\overline{Q_R}$ output.
ECL COMMON	– The collector common for the ECL output stage. The collector common may be tied to +5.0V, but normally it is tied to the circuit ground for standard ECL outputs.
$-V_S$	– Negative supply terminal, nominally −5.2V.
R_S	– R_S is the reference current setting terminal. An external setting resistor, R_{SET}, connected between R_S and $-V_S$ determines the internal reference current. See C_S ($250\Omega \le R_{SET} \le 50k\Omega$).
GROUND	– The ground return for the TTL and analog inputs.
LATCH ENABLE	– Transparent TTL latch control line. A logic HIGH on the LATCH ENABLE freezes the digital code at the logic inputs. A logic LOW on the LATCH ENABLE allows the internal current levels to be continuously updated through the logic inputs D_0 thru D_7.
D_0 (LSB)	– One of eight digital inputs used to set the programmed delay. D_0 (LSB) is the least significant bit of the digital input word.
D_3–D_1	– One of eight digital inputs used to set the programmed delay.

ANALOG DEVICES

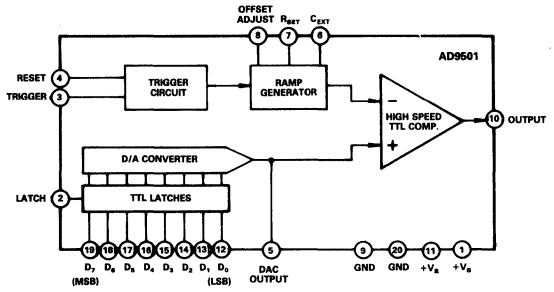
Digitally Programmable Delay Generator

AD9501

FEATURES
Single +5 V Supply
TTL and CMOS Compatible
10 ps Delay Resolution
2.5 ns to 10 μs Full-Scale Range
Maximum Trigger Rate 50 MHz
MIL-STD-883-Compliant Versions Available

APPLICATIONS
Disk Drive Deskewing
Data Communications
Test Equipment
Radar I & Q Matching

FUNCTIONAL BLOCK DIAGRAM



GENERAL DESCRIPTION

The AD9501 is a digitally programmable delay generator which provides programmed time delays of an input pulse. Operating from a single +5 V supply, the AD9501 is TTL- or CMOS-compatible, and is capable of providing accurate timing adjustments with resolutions as low as 10 ps. Its accuracy and programmability make it ideal for use in data deskewing and pulse delay applications, as well as clock timing adjustments.

Full-scale delay range is set by the combination of an external resistor and capacitor, and can range from 2.5 ns to 10 μs for a single AD9501. An eight-bit digital word selects a time delay within the full-scale range. When triggered by the rising edge of an input pulse, the output of the AD9501 will be delayed by an amount equal to the selected time delay (t_D) plus an inherent propagation delay (t_{PD}).

The AD9501 is available for a commercial temperature range of 0°C to +70°C in a 20-pin plastic DIP, 20-pin ceramic DIP, and a 20-lead plastic leaded chip carrier (PLCC). Devices fully compliant to MIL-STD-883 are available in ceramic DIPs. Refer to the *Analog Devices Military Products Databook* or current AD9501/883B data sheet for detailed specifications.

NOTES

[1]Absolute maximum ratings are limiting values, to be applied individually, and beyond which the serviceability of the circuit may be impaired. Functional operability is not necessarily implied. Exposure to absolute maximum rating conditions for an extended period of time may affect device reliability.

[2]Typical thermal impedances: 20-lead plastic leaded chip carrier θ_{JA}=73°C/W; θ_{JC}=29°C/W. 20-pin ceramic DIP θ_{JA}=65°C/W; θ_{JC}=20°C/W. 20-pin plastic DIP θ_{JA}=65°C/W; θ_{JC}=26°C/W.

[3]Digital data inputs must remain stable for the specified time prior to the positive transition of the LATCH signal.

[4]Digital data inputs must remain stable for the specified time after the positive transition of the LATCH signal.

[5]Programmed delay (t_D)=0 ns. Maximum self-resetting trigger rate is limited to 6.9 MHz with 100 ns programmed delay. If t_D=0 ns and external RESET signal is used, maximum trigger rate is 23 MHz.

[6]Programmed delay (t_D)=0 ns. In operation, any programmed delays are in addition to the minimum propagation delay (t_{PD}).

[7]Programmed delay (t_D)=0 ns. [Minimum propagation delay (t_{PD})]

[8]Measured from 50% transition point of the RESET signal input to the 50% transition point of the falling edge of the output.

[9]Minimum time from the falling edge of RESET to the triggering input to insure valid output pulse, using external RESET pulse.

[10]Minimum time from triggering event to rising edge of RESET to insure valid output event, using external RESET pulse. Extends to 125 ns when programmed delay is 100 ns.

[11]When self-resetting with a full-scale programmed delay.

[12]Measured from +0.4 V to +2.4 V; source = 1 mA; sink = 4 mA.

[13]Measured from the data input to the time when the AD9501 becomes 8-bit accurate, after a full-scale change in the program delay data word.

[14]Measured from the RESET input to the time when the AD9501 becomes 8-bit accurate, after a full-scale programmed delay.

[15]Supply voltage should remain stable within ±5% for normal operation.

[16]Measured at $+V_S$ = +5.0 V ±5%; specification shown is for worst case.

Specifications subject to change without notice.

EXPLANATION OF TEST LEVELS

AD9501 PIN DESCRIPTIONS

Pin No.	Name	Function
1	$+V_S$	Positive voltage supply; nominally +5 V.
2	LATCH	TTL/CMOS register control line. Logic HIGH latches input data D_0–D_7. Register is transparent for logic LOW.
3	TRIGGER	TTL/CMOS-compatible input. Rising edge triggers the internal ramp generator, and begins the delay cycle.
4	RESET	TTL/CMOS-compatible input. Logic HIGH resets the ramp voltage and OUTPUT.
5	DAC OUTPUT	Output voltage of the internal digital-to-analog converter.
6	C_{EXT}	Optional external capacitor connected to $+V_S$; used with R_{SET} and 8.5 pF internal capacitor to determine full-scale delay range (t_{DFS}).
7	R_{SET}	External resistor to ground, used to determine full-scale delay range (t_{DFS}).
8	OFFSET ADJUST	Normally connected to GROUND. Can be used to adjust minimum propagation delay (t_{PD}); see Theory of Operation text.
9	GROUND	Circuit ground return.
10	OUTPUT	TTL-compatible delayed output pulse.
11	$+V_S$	Positive voltage supply; nominally +5 V.
12–19	D_0–D_7	TTL/CMOS-compatible inputs, used to set the programmed delay of the AD9501 delayed output. D_0 is LSB and D_7 is MSB.
20	GROUND	Circuit ground return.

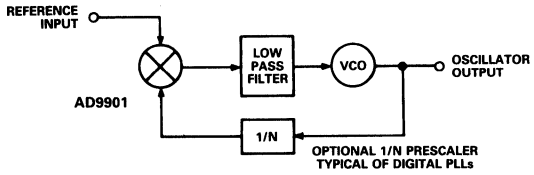
PHASE-LOCKED LOOP



GENERAL DESCRIPTION

The AD9901 is a digital phase/frequency discriminator capable of directly comparing phase/frequency inputs up to 200MHz. Processing in a high speed trench-oxide isolated process, combined with an innovative design, gives the AD9901 a linear detection range, free of indeterminate phase detection zones common to other digital designs.

With a single +5V supply, the AD9901 can be configured to operate with TTL or CMOS logic levels; it can also operate with ECL inputs when operated with a −5.2V supply. The open-collector outputs allow the output swing to be matched to post-filtering input requirements. A simple current setting resistor controls the output stage current range, permitting a reduction in power when operated at lower frequencies.

A major feature of the AD9901 is its ability to compare phase-/frequency inputs at standard IF frequencies without prescalers. Excessive phase uncertainty which is common with standard PLL configurations is also eliminated. The AD9901 provides the locking speed of traditional phase/frequency discriminators, with the phase stability of analog mixers.

The AD9901 is available as a commercial temperature range device, 0°C to +70°C, and as a military temperature device, −55°C to +125°C. The commercial versions are packaged in a 14-pin ceramic DIP and a 20-pin PLCC.

The AD9901 Phase/Frequency Discriminator is available in versions compliant with MIL-STD-883. Refer to the Analog Devices *Military Products Databook* or current AD9901/883B data sheet for specifications.

NOTES
[1]Absolute maximum ratings are limiting values, to be applied individually, and beyond which the serviceability of the circuit may be impaired. Functional operability is not necessarily implied. Exposure to absolute maximum rating conditions for an extended period of time may affect device reliability.
[2]Maximum junction temperature should not exceed +175°C for ceramic packages, +150°C for plastic packages. Junction temperature can be calculated by:

$t_J = PD\ (\theta_{JA}) + t_A = PD\ (\theta_{JC}) + t_C$

where:
PD = power dissipation
θ_{JA} = thermal impedance from junction to air (°C/W)
θ_{JC} = thermal impedance from junction to case (°C/W)
t_A = ambient temperature (°C)
t_C = case temperature (°C)
typical thermal impedances:
AD9901 Ceramic DIP = θ_{JA} = 74°C/W; θ_{JC} = 21°C/W
AD9901 LCC = θ_{JA} = 80°C/W; θ_{JC} = 19°C/W
AD9901 PLCC = θ_{JA} = 88.2°C/W; θ_{JC} = 45.2°C/W
[3]V_L = +0.4V; V_H = +2.4V.
[4]R_{SET} = 47.5Ω; R_L = 182Ω.
[5]Includes load current of 10mA (load resistors = 182Ω).
[6]Supply should remain stable within ±5% for normal operation.

Specifications subject to change without notice.

85 MHz Direct Digital Synthesizer

AD9955

FEATURES

85 MHz Minimum Clock Rate
32-Bit Phase Accumulator
12-Bit Sine Output
>90 dB Spurious Free Dynamic Range
Continuous Frequency Update
On-Board Data Ready Signal

APPLICATIONS

Frequency Synthesizers
DDS Tuning
Digital Demodulation
FM Modulators

GENERAL DESCRIPTION

The AD9955 is a 85 MHz direct digital synthesizer for frequency synthesis applications. It comprises a 32-bit phase accumulator and a 15-bit phase-to-12-bit sine amplitude converter. The control logic is CMOS compatible, and the clock input is TTL. CMOS outputs are latched on board, and a data ready signal is provided.

Designed for applications in communications, instrumentation, and military systems, the AD9955 can be combined with a clock reference and a DAC such as the AD9713B or AD9721 to form a digitally-controlled analog frequency reference.

The AD9955 is available in an 80-lead plastic quad flatpack (PQFP) for commercial (0°C to +70°C) temperature range applications. Contact the factory for information concerning the availability of a military temperature range device.

NOTES
[1]Includes F[0:31], PSEL, BREN, FCLD, CIN, TGLE, BRCLK, TCMS, and RST0.
[2]Only the clock (CLK) is TTL compatible.
[3]f_{OUT} = 1/2 f_{CLK}. See performance curves.
[4]Nominal conditions (V_{IH} = 3.4 V; V_{IL} = 0.4 V).
[5]Based on minimum clock pulse width duty cycle (68% HIGH @ 85 MHz).
[6]This specification defines the maximum rate at which the output frequency tuning word (F[0:31]) can be updated.
[7]Referenced to 2.5 V point of rising edge of BRCLK, specified for F[0:31], BREN.
[8]Referred to rising edge of CLK, specified for FCLD. CIN setup time is typically 1.2 ns, specified for FCLD, CIN.
[9]Referred to 1.6 V point of the rising edge of CLK. See Timing Diagram.
[10]Referenced to 1.6 V point of the rising edge of CLK for 1.6 V point of the rising/falling edge of SIN [0:11]; or the falling edge of DRDY. Load is shown below.
[11]Referenced from 1.6 V point of the rising/falling edge of SIN[0:11] to 1.6 V point of the falling edge of DATA READY. Specified driving AD9713B; no additional capacitive load.
[12]Referenced from 1.6 V point of rising edge of CLK to 1.6 V point of the rising/falling edge of COUT.
[13]Based on proprietary phase-to-sine algorithm, TGLE HIGH.
[14]Referred to CLK for FCLD high. See Timing Diagram.

EXPLANATION OF TEST LEVELS

Test Level

I – 100% production tested.
II – 100% production tested at +25°C; parameter is guaranteed by design and characterization at temperature extremes.
III – Sample tested only.
IV – Parameter is guaranteed by design and characterization testing.
V – Parameter is a typical value only.

Parameters based on characterization testing have limits based on 6 sigma of a normal distribution; typical values are the mean of the distribution.

ABSOLUTE MAXIMUM RATINGS[1]

Supply Voltage ($+V_S$) . . . . . −0.5 V to +7 V
Input Voltage . . . . . −0.5 V to $+V_S$ +0.5 V
Output Voltage Swing . . . . . −0.5 V to $+V_S$ +0.5 V
Operating Temperature Range (Ambient) . . . . . 0°C to +70°C
Maximum Junction Temperature[2] . . . . . +150°C
Storage Temperature Range . . . . . −65°C to +150°C
Lead Temperature (soldering, 10 seconds) . . . . . +250°C

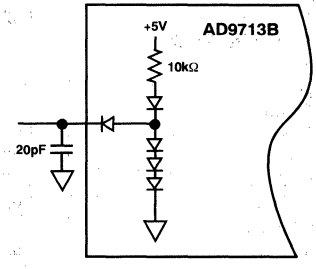
NOTES
[1]Absolute maximum ratings are limiting values to be applied individually, and beyond which the serviceability of the circuit may be impaired. Functional operability is not necessarily implied. Exposure to absolute maximum rating conditions for an extended period of time may affect device reliability.
[2]Typical thermal impedance; part soldered in place:
θ_{JA} = 62°C/W
θ_{JC} = 7°C/W.

ORDERING GUIDE

Model	Temperature Range	Package Description	Package Option[1]
AD9955KS-66[2]	0°C to +70°C	80-Terminal Plastic Quad Flatpack	S-80
AD9955KS-6[3]	0°C to +70°C	80-Terminal Plastic Quad Flatpack	S-80
AD9955/PCB	N/A	DDS Evaluation Board	

NOTES
[1]For outline information see Package Information section.
[2]Model AD9955KS-66 units are shipped in a standard JEDEC tray; minimum order quantity is 66 units (1 full tray).
[3]AD9955KS-6 units are shipped in a nonstandard tray; minimum order quantity is 6 units (1 full tray). Three nonstandard trays will fit in a standard JEDEC tray outline, allowing use with standard assembly equipment. Contact factory for details.

NOTE: All units are dry packed to inhibit moisture absorption. Units which are exposed to air for more than 48 hours should be baked for 24 hours at +125°C prior to assembly.

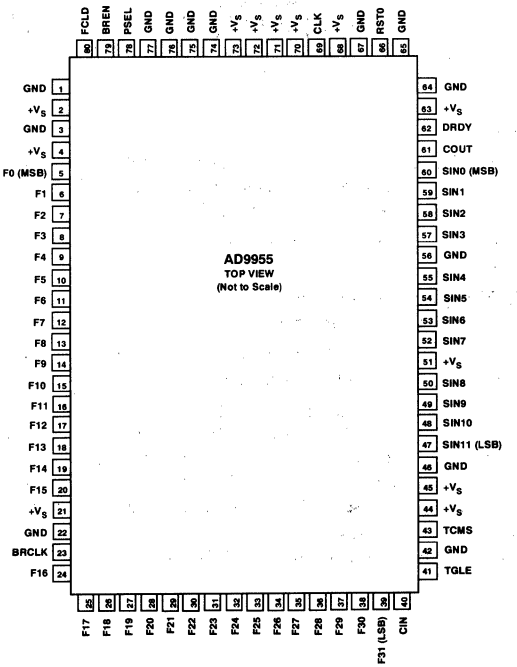


AD9955 Load Circuit

AD9955 PIN DESCRIPTIONS

Name	Description
GND	Ground Reference Voltage Connection.
$+V_S$	Positive voltage power connection, nominally +5 V.
BRCLK	Buffer Register Clock. Data inputs are loaded into the Frequency Control Word Buffer Register on the rising edge of BRCLK when register is enabled (BREN input at Logic "1").
CLK	System Clock. Continuous TTL signal for synchronizing all internal operations, except loading of Frequency Control Word Buffer Register; rising edge initiates synchronization.
F[0:31]	32 parallel data inputs for loading frequency tuning word.
BREN	Buffer Load Enable Signal. Enables loading of data into the Frequency Control Word Buffer Register. If BREN is logic "0," register retains its contents. If BREN is Logic "1," theFrequency Control Word Buffer Register either (1) parallel loads the data present at F[0:31] inputs (PSEL = HIGH) or (2) serially shifts data present at F[31] input (PSEL = LOW).
FCLD	Frequency Control Load Enable Signal. FCLD = HIGH enables loading of data from Frequency Control Word Buffer Register into Frequency Control Register. Loading takes place on next rising edge of CLK signal. FCLD = LOW disables loading of data.
DRDY	Data Ready Signal. Output data (SIN [0:11]) is valid on the rising edge of DRDY, which tracks propagation delay variations of the output data vs. temperature. The duty cycle of DRDY is dependent on the duty cycle of the CLK input. The DRDY signal should be used only for applications which have a very high clock rate (85 Msps) and require operation over a wide temperature range. Normally allowed to float.
CIN	Carry-In signal is provided as the carry input to the least significant bit (LSB) of the 32-bit adder in the phase accumulator. This signal is used as the carry input only if the TGLE signal is a logic zero; carry has 1 LSB weight, and is used for stacking units for 64-bit DDS. Normally tied to ground.
TGLE	Carry Toggle Enable. When HIGH, the CIN signal is disabled, and the Carry-In toggles internally between HIGH and LOW on each clock (CLK) cycle to reduce the worst case spurious response of the digital output signal by 3.92 dB. Normally tied to ground.
TCMS	Twos Complement/Magnitude Mode Select. Selects binary output format of data on SIN[0:11] outputs. If TCMS is a Logic "1," format of output data at SIN[0:11] is in twos complement format. If TCMS is a Logic "0," data is binary unsigned magnitude format. Normally tied to ground.
SIN[0:11]	12 parallel data bits comprising the sine data output. Frequency of the sine data outputs is defined by the Frequency Control Register (Δ phase) as $f_{OUT} = f_{CLK}\left(\frac{\Delta\ phase}{2^{32}}\right)$ Binary data format of 12-bit samples is either twos complement or unsigned magnitude, determined by TCMS signal.
RST0	Reset Phase to Zero Signal. Activates synchronous reset of the Phase Accumulation Register to a binary value of "0," or zero radians. Reset is enabled when RST0 is a Logic "1" and takes place on rising edge of system clock (CLK). Normally low.
COUT	Carry-Out signal output of the 32-bit adder in the phase accumulator; used for stacking two AD9955 units for 64-bit DDS. Normally allowed to float.
PSEL	Parallel/Serial Frequency Control Word Buffer Input Selector. Selects mode for loading the Buffer Register. If a load is enabled (BREN = "1"), and PSEL is a Logic "1," data is parallel loaded into the Frequency Control Word Buffer Register from the F0:31] inputs on the next rising edge of BRCLK. If a load is enabled and PSEL is a Logic "0," data is serially shifted into the Frequency Control Word Buffer Register from the F[31] input on rising edge of BRCLK.

PIN DESIGNATIONS



DIE INFORMATION

Die Dimensions	.215 × 199 × 20.7 (±1) mils

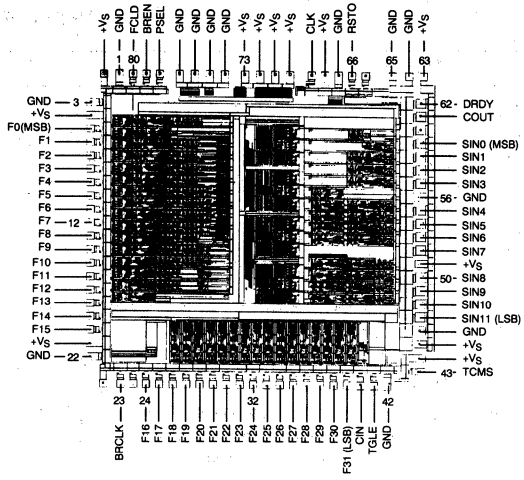
Die Attach	Epoxy
Bond Wire	Gold



AD9955 Chip Layout

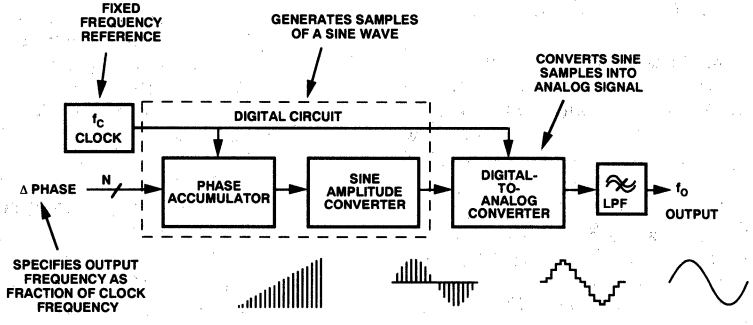


Figure 1. Block Diagram of DDS Generator

DDS

Direct digital synthesis (DDS) is a method of deriving a wide-band, digitally controlled frequency (sine wave) synthesizer from a single reference frequency (system clock).

The circuit has three major components:

1. Phase accumulator
2. Phase-to-amplitude converter
3. Digital-to-analog converter

These major stages and their relationships to one another are illustrated in the block diagram shown above.

The phase accumulator is a digital device which generates the phase increment of the output waveform. Its input is a digital word which (with the reference oscillator) determines the frequency of the output waveform. The output of the phase accumulator stage represents the current phase of the generated waveform. In effect, the accumulator serves as a variable-frequency oscillator generating a digital ramp. The frequency of the signal is defined by Δphase as

$$f_{OUT} = \frac{\Delta phase}{\Delta phase_{MAX}} f_{CLOCK} = \frac{\Delta phase}{2^N} f_{CLOCK}$$

Translating phase information from the phase accumulator into amplitude data takes place in the phase-to-amplitude converter. This is most commonly accomplished by means of a look-up table (LUT) stored in memory, but may be calculated instead using a digital algorithm to minimize circuit complexity and/or increase the update rate.

In the final step of frequency synthesis, amplitude data is converted into an analog signal. This is done by a digital-to-analog (D/A) converter which must have good linearity; low glitch impulse; and fast, symmetrical rise and fall times. When it does, the frequency synthesizer is able to produce a spectrally pure waveform.

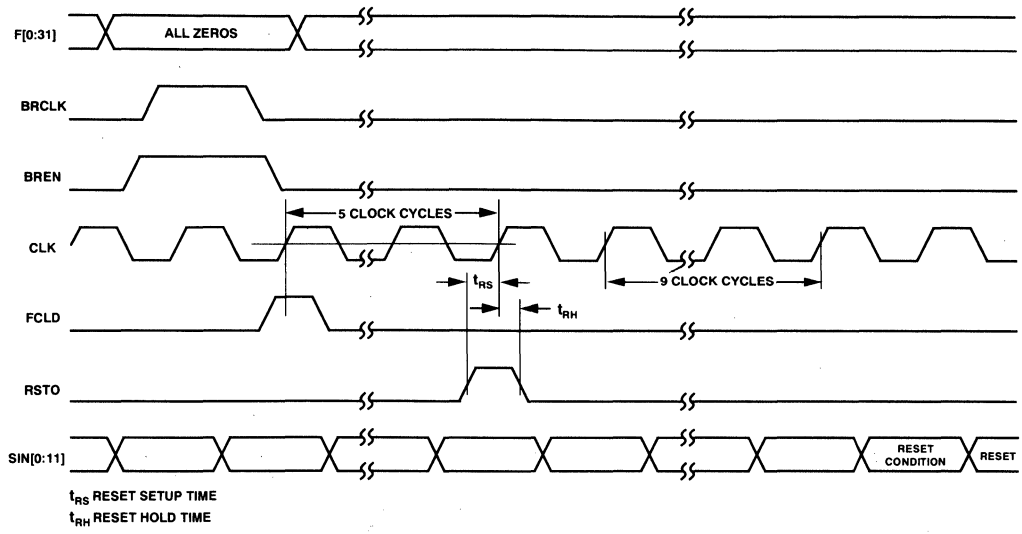

Figure 2. Reset Timing

AD9955 DIRECT DIGITAL SYNTHESIZER

The AD9955 is a digital device which integrates a 32-bit phase accumulator and 15-bit phase to 12-bit sine amplitude converter (see block diagram). The circuit is fabricated in a CMOS process technology, and designed to minimize the number of external devices necessary to implement a high speed DDS system.

Phase Accumulator Architecture

The phase accumulator is comprised of 8 pipelined, 4-bit adder cells to achieve the typical 100 MHz operation. The pipelined accumulator requires the use of input data alignment registers between the frequency control register and the accumulator to maintain the phase-coherent switching characteristics of the DDS. The alignment registers on the 16 least significant bits of the accumulator were eliminated to save power and reduce the number of pipeline delays; this results in a maximum phase discontinuity of 0.005°.

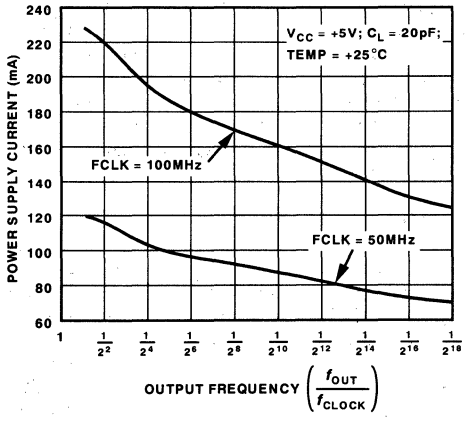

Figure 3. Power Supply Current vs. Output Frequency

The accumulator incorporates carry input and output pins (CIN and COUT) to enable stacking of devices to achieve greater than 32-bit resolution. In normal operation, CIN will be connected to ground, and COUT allowed to float.

An additional feature of the AD9955 accumulator is controlled by the TGLE pin. With this pin tied HIGH, the CIN pin is disabled and the carry input is internally toggled on successive clock cycles. The toggling of the carry input has two major benefits. The theoretical worst case spur is reduced by 3.92 dB, making the worst case spurious free dynamic range of the SIN[0:11] outputs 90.3 dBc. In addition, the DDS spur performance is made more consistent versus frequency due to the randomizing of the errors introduced by possible DAC nonlinearities.

Resetting the AD9955

The synchronous reset function (RST0) resets the output of the phase accumulator to zero radians, allowing the user to initialize the AD9955 from a known state. A reminder: the RSTO signal does not affect the contents of the alignment registers on either side of the adders. To properly reset the AD9955 to zero radians (SIN[0:11] = 1000 0000 0000), perform the following steps in the order listed:

1. Frequency input should be preloaded to zero (F[0:31] = 0; see loading the AD9955).
2. Four clock cycles must pass to clear the prealignment registers.
3. The RSTO signal should go HIGH for at least 12 ns, and meet required setup (t_{RS}) and hold (t_{RH}) times.
4. Nine additional clock cycles must pass to clear the post-alignment registers and allow the new tuning word (0 radians) to propagate through the phase to sine amplitude conversion circuitry.

Critical timing and pipeline delays required for resetting the AD9955 are illustrated in the reset timing diagram. After the RSTO signal is returned to LOW, a new frequency can be

21

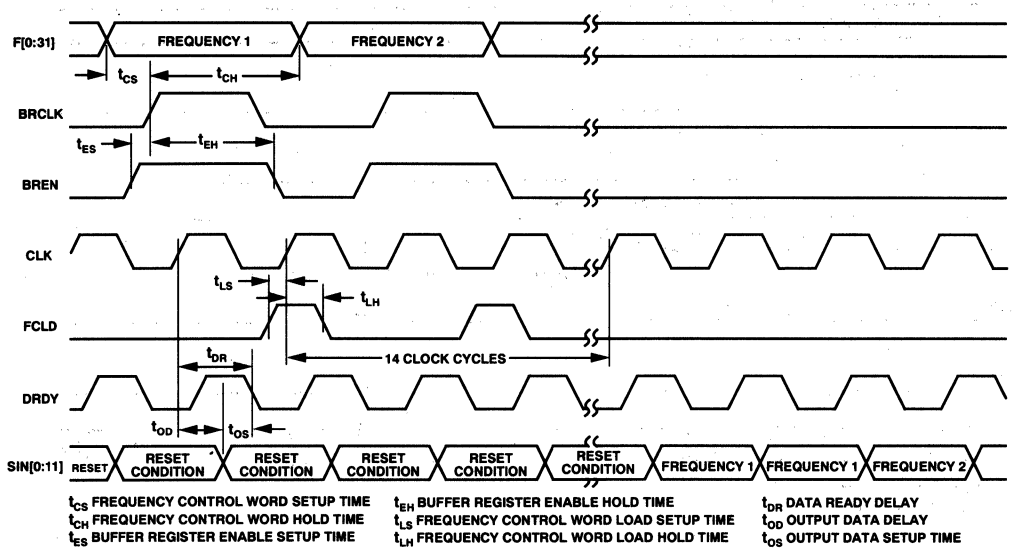

Figure 4. Parallel Mode Timing

loaded into the frequency control register; the SIN[0:11] outputs will remain at the midscale value for 14 clock cycles while the new tuning word propagates through the AD9955.

Loading the Frequency Control Word

For convenience, the frequency control register is double buffered at the inputs to allow asynchronous loading of a new frequency control word. The frequency control word buffer register can be loaded in either parallel (PSEL = HIGH) or serial (PSEL = LOW) mode. The data is clocked on the rising edge of the BRCLK signal when the BREN pin is held HIGH. In serial mode, the data is fed through the LSB (F[31]) and requires multiple clock edges to shift in data.

Once new frequency data is loaded into the frequency control word buffer, it is passed into the frequency control register on the next rising edge of the CLK signal following a HIGH signal on the FCLD pin. The new frequency control word is then used as the input to the phase accumulator and it begins to accumulate at the new rate. The Parallel Mode Timing diagram illustrates the critical timing relationships for loading new frequency data into the AD9955 from the reset condition; these relationships remain the same for any arbitrary condition.

Phase to Sine Architecture

The phase to sine amplitude converter calculates the sine amplitude using a proprietary algorithm for the first 90° of the sine cycle, and takes advantage of the symmetry of the waveform to calculate the remaining quadrants. Only the 15 most significant bits of the phase accumulator output are needed to achieve the 12-bit accuracy of the SIN[0:11] outputs.

In normal operation (TGLE = LOW), the frequency tuning word may take on both odd and even values. Odd frequency input words will result in a spurious free dynamic range (SFDR) of 90.3 dBc, while even frequency words may have spurious frequency content as high as 86.4 dBc. The carry toggle feature discussed above guarantees a worst case SFDR of the frequency tuning words of 90.3 dBc.

The architecture and implementation of the phase to sine algorithm uses several compression techniques to reduce the amount of internal memory required, and to guarantee a minimum throughput rate of 85 MHz, a new benchmark for CMOS DDS circuits. Accordingly, the CLK input is TTL logic compatible, and buffered internally to minimize input capacitance. Although most devices will operate with a 50% duty cycle on CLK input, guaranteed operation at 85 MHz will require adjustment of clock duty cycle (see specification table). All other inputs and outputs are CMOS logic compatible.

SIN Outputs

The SIN[0:11] outputs of the phase to sine conversion circuitry are latched at the output to minimize data skew. The TCMS control signal specifies the format of the output data as either binary unsigned magnitude or two's complement format. The output data is valid on the rising edge of the data ready signal (DRDY), and is designed to track the temperature variation of the output data. The DRDY signal is not recommended for clocking the DAC because of phase uncertainty (jitter). The parallel mode timing diagram also illustrates the timing relationships relevant to capturing the output data, and also the pipeline delays associated with loading a new frequency word. The curves below show the typical propagation delays of SIN[0:11] and DRDY vs. temperature.

SERIAL MODE OPERATION

Serial data is shifted into Pin F31 on the rising edge of the BRCLK. The setup and hold times shown in Figure 4 (Parallel Mode Timing) apply to loading serial data as well. Thirty-two cycles of the BRCLK are needed to shift the entire frequency control word into the Frequency Control Word Buffer Register. Bits are clocked in ascending order, F[31], F[30], F[29] . . . with the MSB clocked in last. A HIGH signal on the FCLD pin allows all 32 bits to pass to the Frequency Control Register on the next rising edge of the CLK.

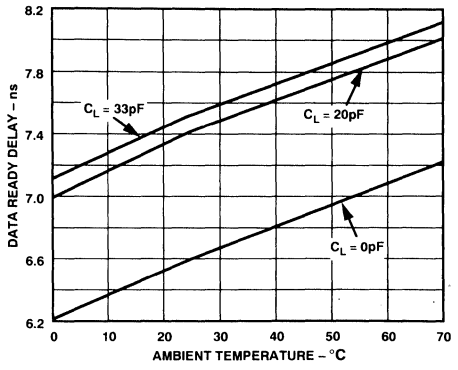

Figure 5. Data Ready Delay vs. Ambient Temperature

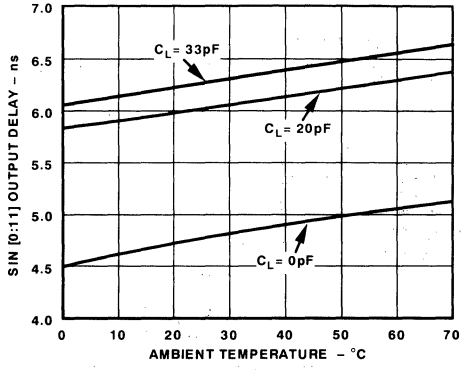

Figure 6. Output Delay vs. Ambient Temperature

Applications Information

The AD9955 can be used in digital demodulation applications to provide a digital frequency reference, or combined with a DAC to provide an analog frequency reference. In the latter application, a DAC with exceptional ac performance is required. The diagram below gives a recommended hookup for a complete direct digital synthesizer employing the AD9955 and the AD9721, a 10-bit 100 Msps DAC.

As in all high speed applications, proper layout is critical; it is particularly important when both analog and digital signals are involved. Analog signal paths should be kept as short as possible, and properly terminated to avoid reflections.

Digital signal paths should also be kept short, and run lengths matched to avoid propagation delay mismatch. In the diagram, series resistors (130 ohms) are inserted in the connections between the SIN[0:9] outputs of the AD9955 and the data inputs of the AD9721 (D_1–D_{10}) to reduce data feedthrough effects and to insure that the setup and hold times of the AD9721's input register are met over the commercial temperature range (0°C to +70°C).

Layout of the ground circuit is a critical factor. A single, low impedance ground plane will reduce noise on the circuit ground. Power supplies should be capacitively coupled to the ground plane to reduce noise in the circuit. Multilayer boards allow designers to lay out signal traces without interrupting the ground plane, and provide low impedance power planes.

Evaluation Board

An evaluation board is available which combines the AD9955 and either the AD9713B, an 80 Msps 12-bit DAC, or the AD9721, a 10- bit 100 Msps DAC, both of which are supplied with the board. This simplifies the task of evaluating and characterizing the DDS synthesizer. The block diagram shown in Figure 9 illustrates its operation. For more information, please consult the AD9955/PCB data sheet.

GENERAL DESCRIPTION

Analog Devices offers a broad line of modular ac/dc power supplies that provide both OEMs and designers a reliable, easy to use, low-cost solution to their power requirements. Models are available in PC mountable and chassis mountable designs with 5 volt to 15 volt (single, dual, triple) outputs and current ratings from 100 mA to 5 amps. Since these modular supplies are fully encapsulated, no trimming or external component selection is necessary; simply mount the unit, connect power and output leads, and you're on the air! Most Analog Devices' power supplies are available from stock in both large and small quantities with substantial discounts being applied to large quantity orders.

AC/DC POWER SUPPLY FEATURES

- Current Limit Short Circuit Protection
- PC Mounted and Chassis Mounted Versions
- Single (+5 V), Dual (±15 V), and Triple (±15 V/+5 V) Output Supplies
- Current Outputs:
  100 mA to 500 mA for Dual and Triple Output Supplies
  1000 mA to 5000 mA for Single Output Supplies
- Wide Input Voltage Range
- Low Output Ripple and Noise
- Excellent Line & Load Regulation Characteristics
- High Temperature Stability
- Free-Air Convection Cooling; No External Heat Sink Required

GENERAL SPECIFICATIONS

Power Requirements

Input Voltage Range:	105 V ac to 125 V ac
Frequency:	50 Hz to 250 Hz

Electrical Specifications

Temperature Coefficient:	0.02%/°C
Output Voltage Accuracy:	±2%, max See Specifications Table
Breakdown Voltage:	500 V rms, min
Isolation Resistance:	50 MΩ
Short Circuit Protection:	All ac/dc power supplies employ current limiting. They can withstand substantial overload including direct short. Prolonged operation should be avoided since excessive temperature rises will occur.

Environmental Requirements

Operating Temperature Range:	−25°C to +71°C
Storage Temperature Range:	−25°C to +85°C

SPECIFICATIONS – Typical @ +25°C and 115 V ac 60 Hz unless otherwise noted*

22

Power Supplies
Modular DC/DC Converters

GENERAL DESCRIPTION

Analog Devices' line of compact dc/dc converters offers system designers a means of supplying a reliable, easy to use, low cost solution to a variety of floating (analog and digital) power applications. These devices provide high accuracy, short circuit protected, regulated outputs with very low output noise and ripple characteristics.

Nine models are offered in four power levels of 1 watt, 1.8 watts, 4.5 watts and 6 watts. Input voltage versions include 5 volt, 12 volt and 28 volt with output ranges as follows: +5 volt, ±12 volts and ±15 volts at ±40 mA to 1000 mA output current capability.

Most models are high efficiency (typically over 60% at full load) and feature complete 6-sided continuous shielding for EMI/RFI protection. A π-type input filter is contained, in some models, which virtually eliminates the effects of reflected input ripple current. Most Analog Devices' dc/dc converters are available from stock in both large and small quantities with substantial discounts being applied to large quantity orders.

DC/DC POWER SUPPLY FEATURES

- Inaudible (>20 kHz) Converter Switching Frequency
- Continuous, Six-Sided EMI/RFI Shielding Except on 1 Watt and 1.8 Watt Models
- Output Short Circuit Protection (Either Output to Common)
- Automatic Restart After Short Condition Removed
- Automatic Starting with Reverse Current Injected into Outputs
- Low Output Ripple and Noise
- High Temperature Stability
- Free Air Convection Cooling
  No external heat sink or specification derating is required over the operating temperature range.

GENERAL SPECIFICATIONS FOR 1 W AND 1.8 W MODELS

Line Regulation – Full Range: ±0.3% (±1% max, 949)
Load Regulation – No Load to Full Load: ±0.4% (±0.5% max, 949)
Output Noise and Ripple: 20 mV p–p, with 15 μF tantalum capacitor across each output (2 mV rms max, 949)
Breakdown Voltage: 300 V dc min (500 V dc min, 949)
Input Filter Type: π
Operating Temperature Range: −25°C to +71°C
Storage Temperature Range: −40°C to +125°C (+100°C, 949)
Fusing: If input fusing is desired, we recommend the use of a slow blow type fuse that is rated at 150%–200% of the dc/dc converter's full load input current.

GENERAL SPECIFICATIONS FOR 4.5 W AND 6 W MODELS

Line Regulation – Full Range: ±0.07% max (±0.02% max, 960 Series) (±0.1% max, 943)
Load Regulation – No Load to Full Load: ±0.07% max (±0.02% max, 960 Series) (±0.1% max, 943)
Output Noise and Ripple: 1 mV rms max
Breakdown Voltage: 500 V dc min
Input Filter Type: π
Operating Temperature Range: −25°C to +71°C
Storage Temperature Range: −40°C to +125°C
Fusing: If input fusing is desired, we recommend the use of a slow blow type fuse that is rated at 150%–200% of the dc/dc converter's full load input current.

SPECIFICATIONS – Typical @ +25°C at nominal input voltage unless otherwise noted*

Model	Output Voltage Volts	Output Current mA	Input Voltage Volts	Input[1] Voltage Range Volts	Input Current Full Load	Output Voltage Error max	Temperature Coefficient /°C max	Efficiency Full Load min	Dimensions Inches

NOTES
[1]Models 940 and 941 will deliver up to 120 mA output current (and Model 943 will deliver up to 600 mA) over an input voltage range of 4.65 V dc and 5.5 V dc.
*Consult Analog Devices Power Supplies Catalog for additional information.
**Single-ended or unbalanced operation is permissible such that total output current load does not exceed a total of 120 mA.
Specifications subject to change without notice.

Appendix Contents

Ordering Guide

INTRODUCTION

This Ordering Guide should make it easy to order Analog Devices products. It will help you:

1. Find the correct part number for the options you want.
2. Get a price quotation and place an order with us, or one of our authorized distributors.
3. Know our warranty for components and subsystems.

For answers to further questions, call the nearest sales office (listed on pages 24–16 and 24–17) or our main office in Norwood, Massachusetts U.S.A. (617-329-4700).

MODEL NUMBERING

In this reference manual many of the data sheets for products having a number of standard options contain an Ordering Guide. Use it to specify the correct part number for the exact combination of options you want. Two model numbering schemes are used by Analog Devices. The first model numbering scheme is used for designating standard Analog Devices monolithic and hybrid products. The second scheme is used by our Precision Monolithics Division (formerly PMI) as designators for its product line.

Figure 1 shows the form of model number used for our proprietary standard monolithic ICs and many of our hybrids. It consists of an "AD" (Analog Devices) prefix, a 3-to-5-digit number,* an alphabetic performance/temperature-range designator and a package designator. One or two additional letters may immediately follow the digits ("A" for second-generation redesigned ICs, "DI" for dielectrically isolated CMOS switches, e.g., AD536AJH, AD7512DIKD).

Figure 2 shows a different numbering scheme used by our Precision Monolithics Division. This numbering scheme starts with a prefix which designates the device type and model number. It is then followed by a suffix consisting of alphabetic designators (as applicable) to indicate additional functional designations or options and packaging options.

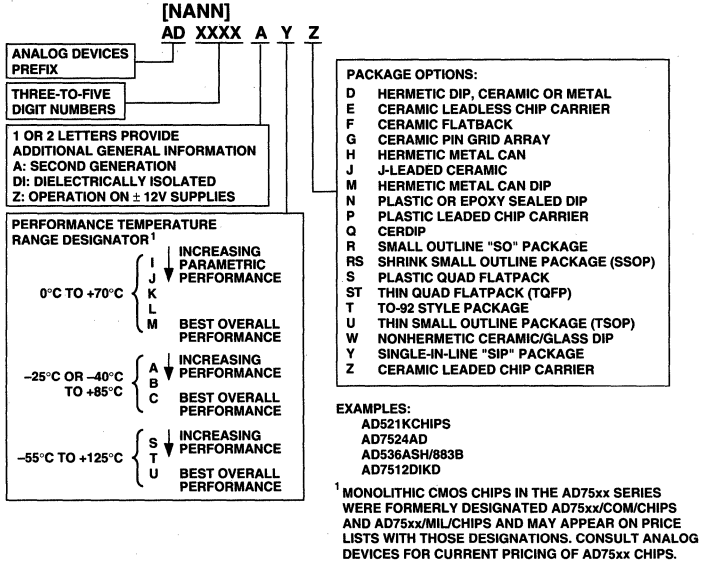

Figure 1. Model-Number Designations for Standard Analog Devices Monolithic and Hybrid IC Products. S, T and U Grades Have the Added Suffix /883B for Devices that Qualify to the Latest Revision of MIL-STD-883, Level B.

*For some models, the combination [digit][letter] [two or three digits] is used instead of ADXXXX, e.g., 2S80.

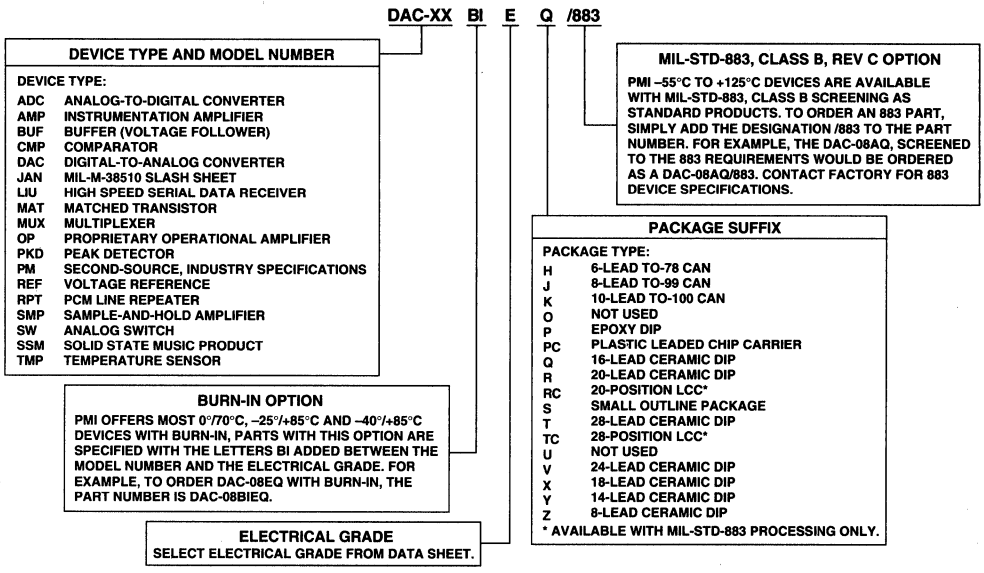

Figure 2. Precision Monolithics Division's Product Designations

ORDERING FROM ANALOG DEVICES

When placing an order, please provide specific information regarding model type, number, option designations, quantity, ship-to and bill-to address. Prices quoted are list; they do not include applicable taxes, customs, or shipping charges. All shipments are F.O.B. factory.

Eligible customers may place their orders through our regional customer service centers by dialing 1-800-262-5645 (U.S.A. only) or through our representatives or authorized distributors. (The telephone numbers for our representatives or authorized distributors are listed on pages 24–16 and 24–17.) Analog Devices' minimum order value is $500.00.

WARRANTY AND REPAIR CHARGE POLICIES

All Analog Devices, Inc., products are warranted against defects in workmanship and materials under normal use and service for one year from the date of their shipment by Analog Devices, Inc., except that components obtained from others are warranted only to the extent of the original manufacturers' warranties, if any, except for component test systems, which have a 180-day warranty. This warranty does not extend to any products which have been subjected to misuse, neglect, accident, or improper installation or application, or which have been repaired or altered by others. Analog Devices' sole liability and the Purchaser's sole remedy under this warranty is limited to repairing or replacing defective products. (The repair or replacement of defective products does not extend the warranty period. This warranty does not apply to components which are normally consumed in operation or which have a normal life inherently shorter than one year.) Analog Devices, Inc., shall not be liable for consequential damages under any circumstances.

THE FOREGOING WARRANTY AND REMEDY ARE IN LIEU OF ALL OTHER REMEDIES AND ALL OTHER WARRANTIES, WRITTEN OR ORAL, STATUTORY, EXPRESS, OR IMPLIED, INCLUDING ANY WARRANTY OF MERCHANTABILITY OR FITNESS FOR A PARTICULAR PURPOSE.

Product Families Still Available

The information published in this Reference Manual is intended to assist the user in choosing components for the design of *new* equipment, using the most cost-effective products available from Analog Devices. The popular product types listed below may have been designed into your circuits in the past, but they are no longer likely to be the most economic choice for your new designs. Nevertheless, we recognize that it is often a wise choice to refrain from redesigning proven equipment, and we are continuing to make these products available for use in existing designs. Data sheets on these products are available upon request.

DSP Reference Manual Product Families

Analog Devices offers a wide variety of high performance DSP products. These products are not included in this manual because our new *Digital Signal Processing Reference Manual* is scheduled for publication in late 1994. That reference manual will provide complete data sheets for the design-in products listed below.

Substitution Guide

The products listed in the left-hand column are no longer available from Analog Devices. In many cases, comparable functions and performance may be obtained with newer models, but—as a rule—they are not directly interchangeable. The closest recommended Analog Devices equivalent, physically and electrically, is listed in the right-hand column. If no equivalent is listed, or for further information, contact your local sales office.

Technical Publications

Analog Devices provides a wide array of FREE technical publications. These include data sheets, reference manuals and catalogs, application notes and guides, and three serial publications: *DSPatch*™, a newsletter about digital signal-processing (applications); *Analog Briefings*®, current information about products for military/avionics and the status of reliability at ADI; and *Analog Dialogue,* our technical magazine, with in-depth discussions of products, technologies and applications.

In addition to the free publications, a group of technical reference books containing a wealth of tutorial material are available at reasonable cost. Subsystem chip sets are supported with hardware, software, and user documentation, at prices related to content.

An overview of Analog Devices is available in a 20-page brochure entitled: *Analog.Digital.Solutions.* It discusses: a vision of the future and the key role of signal processing using analog, mixed-signal, and digital ICs; what we offer electronic OEMs in standard-function ICs and in devices for such specialized markets as computers, communications, transportation and industry; as well as our capabilities and resources, our commitment to customer support and satisfaction, the global scale of our business, and our commitment to the future.

Brief descriptions of typical technical publications appear below. For copies of any items, to subscribe to any of our free serials or to request any other publications, please get in touch with your nearest sales office or the Analog Devices literature center; phone (617) 461-3392; toll free in U.S., 800-262-5643; or fax (617) 821-4273.

REFERENCE MANUALS AND CATALOGS

Data Acquisition Products Reference Manuals

These databooks contain selection guides, data sheets and other useful information about all Analog Devices ICs, hybrids, modules and subsystem components recommended for new designs. In the current series:

AMPLIFIER REFERENCE MANUAL—1992. Data sheets and selection guides to Operational Amplifiers, Comparators, Instrumentation Amplifiers, Isolation Amplifiers, Mixed-Signal ASICs, Power Supplies.

APPLICATIONS REFERENCE MANUAL—1993. A 1,344-page collection of 210 application notes, technical articles, and other design tutorials on such topics as audio and video circuits, A/D and D/A conversion, data acquisition and signal conditioning, digital signal processing, sigma-delta conversion, and much more. Cross-indexed by topic, product, subject, and application-note number.

SPECIAL LINEAR REFERENCE MANUAL—1992. Data sheets and selection guides to Analog Multipliers/Dividers, Signal Compression Components, RMS-to-DC Converters, Mass Storage Components, ATE Components, Special Function Components, Matched Transistors, Temperature Sensors, Signal Conditioning Components, Automotive Components, Digital Signal Processing Products, Mixed-Signal ASICs, Power Supplies.

DATA CONVERTER REFERENCE MANUAL—1992: Volumes 1 and 2. Data sheets and selection guides on A/D and D/A Converters, V/F and F/V Converters, Synchro/Resolver-to-Digital Converters, Sample/Track-Hold Amplifiers, Switches and Multiplexers, Voltage References, Data-Acquisition Subsystems, Analog I/O Ports, Communications Products, Bus Interface and I/O Products, Application-Specific ICs, Digital Panel Meters, Power Supplies.

MILITARY/AEROSPACE REFERENCE MANUAL—1994. Information and data on products available with processing in accordance with MIL-STD-883. Data sheets and selection guides on Operational Amplifiers, A/D and D/A Converters, Digital Signal Processing, Instrumentation Amps, Multipliers/Dividers, V/F & F/V Converters, Switches & Multiplexers, Sample/Track-Hold Amplifiers, Voltage References and Special Function Components.

*POWER SUPPLIES**—Linear Supplies •DC-DC Converters. 12-page Short Form Catalog listing AC/DC Power Supplies, Modular DC/DC Converters, Power-Supply Test Procedures, Transients, Thermal Derating, Mechanical Outlines of Packages and Sockets.

APPLICATION NOTES

Available individually upon request:

Accelerometers

"Compensating for the 0-g Offset Drift of the ADXL50 Accelerometer" [AN-380]
"Increasing the Frequency Response of the ADXL50" [AN-377]
"Mounting Considerations for the ADXL50" [AN-379]
"Reducing the Average Power Consumption of the ADXL50" [AN-378]
"Using the ADXL50 Accelerometer in Low-g Applications" [AN-374]
"Using the ADXL50EM Accelerometer Evaluation Module" [AN-376]

A/D Converters

"AD671 12-Bit, 2-MHz ADC Digitizes CCD Outputs for Imaging Applications" [AN-298]
"AD7672 Converter Delivers 12-Bit 200-kHz Sampling Systems" [AN-294]
"Asynchronous Clock Interfacing with the AD7878" [AN-291]
"Bipolar Operations with the AD7572" [E1010A]
"Circuit Delivers for 16-Bit, 150-kHz Multichannel Sampling System" [AN-341]
"Evaluation Board for the AD7701/AD7703 Sigma-Delta A/D Converters" [AN-368]
"Evaluation Board for the AD7711 24-Bit, Sigma-Delta Converter" [AN-366]
"Evaluation Board for the AD7712 24-Bit, Sigma-Delta Converter" [AN-365]
"Evaluation Board for the AD7713 24-Bit, Sigma-Delta Converter" [AN-367]
"FIFO Operation and Boundary Conditions in the AD1332 and AD1334" [E1355]
"How to Obtain the Best Performance from the AD7572" [E1038]
"Implement Infinite Sample-and-Hold Circuits Using Analog Input/Output Ports" [AN-284]

Analog Briefings is a registered trademark of Analog Devices, Inc.
DSPatch is a trademark of Analog Devices, Inc.
*This publication is available in North America only.

"Simple Circuit Provides Ratiometric Reference Levels for AD782x Family of Half-Flash ADCs" [AN-299]
"Simultaneous and Independent Sampling of Analog Signals with the AD1334" [E1358]
"The AD7574 Analog-to-Microprocessor Interface" [AN-293]
"Using Multiple AD1334s in Many-Channel Synchronous Sampling Applications" [AN-295]

Amplifiers

"A Balanced-Input High-Level Amplifier" [AN-112]
"AD9617/AD9618 Current-Feedback Amplifier Macro-Models" [AN-259]
"An IC Amplifier User's Guide to Decoupling, Grounding, and Making Things Go Right for a Change" [AN-202]
"An Unbalanced Virtual-Ground Summing Amplifier" [AN-113]
"Precision Surface Measurements Using the AD2S58" [E1486]
"Applications of High-Performance BiFET Op Amps" [E727]
"JFET-Input Amps Are Unrivalled for Speed and Accuracy" [AN-108]
"Low-Cost Two-Chip Voltage-Controlled Amplifier and Video Switch" (AD539) [AN-213]

Analog Signal-Processing and Measurement

"A Function Generator and Linearization Circuit Using the AD7569" [AN-285]
"RMS-to-DC Converters Ease Measurement Tasks" [AN-268]
"Understanding and Applying the AD7341/AD7371 Switched-Capacitor Filters" [AN303]

Audio

"A Balanced Mute Circuit for Audio Mixing Consoles" [AN-122]
"A Constant-Power 'Pan' Control Circuit for Microphone Audio Mixing" [AN-123]
"A High-Performance Compandor for Wireless Audio Systems" [AN-133]
"An Automatic Microphone Mixer" [AN-134]
"A Two-Channel Dynamic Filter Noise Reduction System" [AN-125]
"High Performance Stereo Routing Switcher" [AN-121]
"Interfacing Two 16-Bit AD1856 (AD1851) Audio DACs with the Philips SAA7220 Digital Filter" [AN-207]

D/A Converters

"AD7528 Dual 8-Bit CMOS DAC" [AN-318]
"Analog Panning Circuits Provide Almost Constant Output-Power" [AN-206]
"Circuit Applications of the AD7226 Quad CMOS DAC" [AN-317]
"Dynamic Performance of CMOS DACs in Modem Applications" [AN-329]
"8th Order Programmable Low-Pass Filter Using Dual 12-Bit DACs" [AN-209]

"Low Cost Two-Chip Voltage-Controlled Amplifier and Video Switch." (AD539) [AN-213]

FREE APPLICATION GUIDES AND BROCHURES

Amplifier Products Cross-Reference Guide. A 54-page short form guide to amplifier selection. Includes selection trees, ordering information, model numbering system, and package information, cross-reference to amplifier products from other manufacturers, and military amplifier product information, plus a list of sales offices and distributors.

The Analog Devices family of high-speed op amps. A 6-page selection guide to high-speed op amps.

The Analog Devices family of instrumentation amplifiers. A 6-page selection guide to instrumentation amplifiers.

The Analog Devices family of low-noise op amps. A 6-page selection guide to low-noise op amps.

The Analog Devices family of precision op amps. A 6-page selection guide to precision op amps.

The Analog Devices family of single-supply op amps. A 6-page selection guide to single-supply op amps.

ATE Components. A 20-page brochure describing Analog Devices' capabilities and application-specific standard products for pin electronics in automated testing. Includes descriptions of Delay Generators, Pin Drivers, Active Load, Comparators, Parametric Measurement Components, and Level-Setting Components.

The Best of Analog Dialogue, 1967 to 1991. A 224-page bonus edition containing 52 articles excerpted from the first 25 years of *Analog Dialogue*. Included are articles of lasting interest on practice, techniques, ideas, and applications, as well as articles that introduced landmark products.

ESD Prevention Manual—Protecting ICs from electrostatic discharges. Thirty pages of information that will assist the reader in implementing an appropriate and effective program to assure protection against electrostatic discharge (ESD) failures.

High-Speed Op Amp Sliding Selection Guide. A slide rule for selecting op amps by bandwidth or viewing characteristics by model number. Lists dynamic specs such as slew rate, settling time, differential gain and phase, voltage and current noise, supply voltage and current, and many more.

Instrumentation Amplifier Application Guide, by Charles Kitchin and Lew Counts. Its 44-pages include basic instrumentation-amplifier ("in-amp") theory, design considerations, applications, specifications, and products—plus a brief bibliography and two indexes (by topic and by device model number).

Multiple Digital-to-Analog Converter Integrated Circuits Selection Guide. A 32-page guide for the designer who wants to save space and cost in applications calling for from two to eight or more DACs and resolutions from 6 to 18 bits. Devices include triple 6-, 8-, and 10-bit video DACs, dual 18-bit audio DACs, 8-bit octuples, and 12- and 14-bit quads.

New Audio Signal Processing Integrated Circuits, including Op Amps, DSP microcomputers, Codecs, Line Driver & Receiver, VCA, Preamps, Switches, Decoders, Asynchronous sample-rate converters, Stereo ADCs. A 12-page brochure.

Personal Sound Architecture. An 8-page brochure describing a programmable architecture for integrating sound into personal computers using software-based technologies and IC chipsets (including Analog Devices DSPs, codecs, and other peripherals) for sound cards.

RMS-to-DC Conversion Application Guide 2nd Edition by C. Kitchin and L. Counts (1986—61 pages). RMS-DC Conversion: Theory, Basic Design Considerations; RMS Application

Circuits; Testing Critical Parameters; Input Buffer Amplifier Requirements; Programs for Computing Errors, Ripple and Settling Time.

Sampling Analog-to-Digital Converter Integrated Circuits—1992 Short Form Selection Guide. Its 28 pages cover 35 different models with resolutions from 8 to 16 bits, and 12-bit resolution up to 20 Msps. Besides block diagrams and key specs of each product, the booklet includes a detailed discussion of selection issues and a selection table sorted by resolution and speed.

Solutions for Cellular Radio Base Stations, 6-page reference guide—describes system architectures for cellular, other wireless, and satellite VSAT stations and lists suitable ADI components for each stage of the signal chain; includes all-digital systems using DSP technology.

*Surface Mount IC.** A 28-page guide to ICs in SO and PLCC packages. Products include op amps, rms-to-dc converters, DACs, ADCs, VFCs, sample-holds and CMOS switches.

A Tutorial in AC Induction and Permanent Magnet Synchronous Motors—Vector Control with Digital Signal Processors. An 80-page Guide, including Overview of AC drives, Synchronous machine operation, Induction motors, Pulse-width modulation, Inverter fed drive scheme, Vector control of AC machines, Field-oriented control of DC motors, Implementation of field-oriented control in DSP, and References.

TECHNICAL REFERENCE BOOKS

Can be purchased in North America from Analog Devices, Inc., at the prices shown.† If more than one book is ordered, deduct a discount of $1.00 from the price of each book. Price of the entire set of 13 books is $235.00—a bargain for your department's library (in effect, the *Amplifier Applications Guide* and *Digital Signal Processing in VLSI* come free). VISA and MasterCard are welcome; phone (617) 461-3392 or fax (617) 821-4273. Or send your check for the indicated amount to Analog Devices, Inc., P.O. Box 9106, Norwood, MA 02062-9106.

NEW—*APPLICATIONS REFERENCE MANUAL.* Norwood MA: Analog Devices, Inc. (1993), 1344 pages, softcover. A collection of 210 application notes, technical articles, and other design tutorials on such topics as audio and video circuits, A/D and D/A conversion, data acquisition and signal conditioning, digital signal processing, sigma-delta conversion and much more. Cross-indexed by topic, product, subject, and application-note number. $9.95

NEW—*SYSTEM APPLICATIONS GUIDE.* Norwood MA: Analog Devices, Inc. (1993), 800 pages, 8 1/2″ × 11″ softcover. Precision sensor signal conditioning and transmission; multiplexing; programmable-gain amplifiers; high-accuracy topics: sample-holds, references, conversion; audio; video; high-speed topics: signals & systems, amplification, ADC selection, interfacing, performance verification; sigma-delta conversion; wide dynamic range; direct digital synthesis, signal computing, motor control. $30.00

NEW—*ADSP-2100 FAMILY APPLICATIONS HANDBOOK, Volume I:* A companion to the ADSP-21000 family of floating-point processors. Introduction; Trigonometric, mathematical, and transcendental functions; Matrix functions; FIR and IIR filters; Multirate filters; Adaptive filters; Fourier transforms; Graphics; Image processing; JTAG downloader; Index. Includes 33 figures, 14 tables, and 61 program listings. $22.00

ADSP-2100 FAMILY USER'S MANUAL. Englewood Cliffs NJ: Prentice Hall (1993). A comprehensive reference for Analog Devices' ADSP-2100 Family, an architectural and code-compatible set of 16-bit fixed-point DSP microprocessors that offer varying levels of feature integration. Topics covered in this manual include: Base architecture—computation units, program sequencer, data-address generators; Integrated on-chip peripherals—serial ports, timer, host interface port, A/D and D/A converters; System hardware and memory interfacing; Programmer's model and instruction-set reference; System design and programming examples. $24.00

AMPLIFIER APPLICATIONS GUIDE, by the Applications Engineering Staff of Analog Devices and edited by Walt Kester, published by Analog Devices (1992). 648 pages of timely and practical information on amplifiers—including operational, audio, instrumentation, video, and log amps. Topics include: Introduction; Precision transducer interfaces; High impedance, low current; Single-supply, low-power; Audio; Filtering, Driving ADCs; Video and other high-speed applications; Nonlinear circuit applications; Unusual applications; Subtleties; Hardware techniques; Simulation; and a complete Index. $20.00

ANALOG-DIGITAL CONVERSION HANDBOOK: Third Edition, by the Engineering Staff of Analog Devices, edited by Daniel H. Sheingold. Englewood Cliffs, NJ: Prentice Hall (1986). A comprehensive guide to A/D and D/A converters and their applications. This third edition of our classic is in hardcover and has more than 700 pages, an Index, a Bibliography, and much new material, including: video-speed, synchro-resolver, V/F, high-resolution, and logarithmic converters, ICs for DSP, and a "Guide for the Troubled." Seven of its 22 chapters are totally new. $32.95

DIGITAL SIGNAL-PROCESSING APPLICATIONS USING THE ADSP-2100 FAMILY, by the Applications Staff of Analog Devices, DSP Division; edited by Amy Mar (628 pages). Englewood Cliffs, NJ: Prentice Hall (1990). Bridge the gap between DSP algorithms and their real-world implementation on state-of-the-art signal processors. Each chapter tackles a specific application topic, briefly describing the algorithm and discussing its implementation on the ADSP-2100 family of DSP chips. Comprehensive source-code listings are complete with comments and accompanied by explanatory text. Programs are listed on a pair of supplementary diskettes—furnished with the book. Application areas include fixed- and floating-point arithmetic, function approximation, digital filters, one- and two-dimensional FFTs, image processing, graphics, LP speech coding, PCM, ADPCM, high-speed modem algorithms, DTMF coding, sonar beam-forming. Additional topics include memory interface, multiprocessing, and host interface. The book can serve as a companion to *Digital Signal Processing in VLSI*. **Now in paperback**; its price includes a diskette. $30.00

*This publication is available in North America only.
†Outside of North America consult your local sales office or distributor.

DIGITAL SIGNAL PROCESSING IN VLSI, by Richard J. Higgins. Englewood Cliffs, NJ: Prentice Hall (1990). An introductory 614-page guide for the engineer and scientist who needs to understand and use DSP algorithms and special-purpose DSP hardware ICs—and the software tools developed to carry them out efficiently. Real-World Signal Processing; Sampled Signals and Systems; The DFT and the FFT Algorithm; Digital Filters; The Bridge to VLSI; Real DSP Hardware; Software Development for the DSP System; DSP Applications; plus Bibliography and Index. $38.00

DIGITAL SIGNAL PROCESSING LABORATORY: Using the ADSP-2101 Microcomputer, by Vinay K. Ingle and John G. Proakis (Northeastern University). Englewood Cliffs, NJ: Prentice Hall (1991). Contents: Introduction to the ADSP-2100/2101 family; ADSP-2101 instruction set overview; Overview of development tools; Getting started with the ADSP-2101; Laboratory experiments using the ADSP-2101; FIR filter implementation; IIR filter implementation; Fast Fourier transform implementation; Applications in communications; Adaptive filters and their applications; References; Index. $24.00

HIGH-SPEED DESIGN SEMINAR, published by Analog Devices (1990). A 496-page guide to the practical application of high-speed semiconductor devices in processing of analog signals. Topics include: data conversion, digital video applications, high-speed sample-holds and operational amplifiers, nonlinear signal processors (including log amps), comparators and pin electronics, time-delay generators, phase-locked loops, direct digital synthesis, computer graphics and RAMDACs, and high-speed techniques. $20.00

MIXED-SIGNAL DESIGN SEMINAR, published by Analog Devices (1991). Contents: Introduction to mixed-signal processing of real-world signals and signal conditioning; Linear and nonlinear analog signal processing; Fundamentals of sampled-data systems; ADCs for DSP applications; DACs for DSP applications; Sigma-delta ADCs and DACs; Digital signal-processing techniques; DSP hardware; Interfacing ADCs and DACs to digital signal processors; Mixed-signal processing applications; Mixed-signal circuit techniques; Index. $22.00

NONLINEAR CIRCUITS HANDBOOK: Designing with Analog Function Modules and ICs, by the Engineering Staff of Analog Devices, edited by Daniel H. Sheingold. Norwood, MA: Analog Devices, Inc. (1974). A 540-page guide to multiplying and dividing, squaring and rooting, rms-to-dc conversion, and multifunction devices. Principles, circuitry, performance, specifications, testing, and application of these devices—contains 325 illustrations. $5.95

TRANSDUCER INTERFACING HANDBOOK: A Guide to Analog Signal Conditioning, edited by Daniel H. Sheingold. Norwood, MA: Analog Devices, Inc. (1980). A book for the electronic engineer who must interface transducers for temperature, pressure, force, level, or flow to electronics, these 260 pages tell how transducers work—as circuit elements—and how to connect them to electronic circuits for effective processing of their signals. $14.50
