MINIMIZING INPUT CURRENT

The AD795 is guaranteed to 1 pA max input current with ±15 volt supply voltage at room temperature. Careful attention to how the amplifier is used will maintain or possibly better this performance.

The amplifier's operating temperature should be kept as low as possible. Like other JFET input amplifier's, the AD795's input current will double for every 10°C rise in junction temperature (illustrated in Figure 6). On-chip power dissipation will raise the device operating temperature, causing an increase in input current. Reducing supply voltage to cut power dissipation will reduce the AD795's input current (Figure 4). Heavy output loads can also increase chip temperature, maintaining a minimum load resistance of 10 kΩ in recommended.

CIRCUIT BOARD NOTES

The AD795 is designed for throughhole mounting on PC boards, using either mini-DIP or surface mount (SOIC). Maintaining picoampere resolution in those environments requires a lot of care. Both the board and the amplifier's package have finite resistance. Voltage differences between the input pins and other pins as well as PC board metal traces will cause parasitic currents (Figure 30) larger than the AD795's input current unless special precautions are taken. Two methods of minimizing parasitic leakages are guarding of the input lines and maintaining adequate insulation resistance.

Figures 31 and 32 show the recommended guarding schemes for follower and inverted topologies. Note that for the mini-DIP, the guard trace should be on both sides of the board. On the SOIC, Pin 1 is not connected, and can be safely connected to the guard. The high impedance input trace should be guarded on both edges for its entire length.

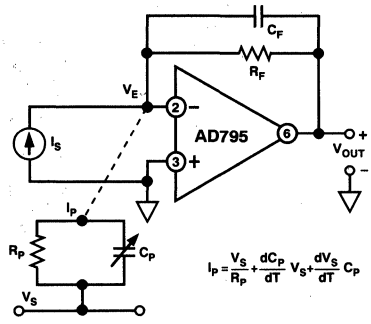

Figure 30. Sources of Parasitic Leakage Currents

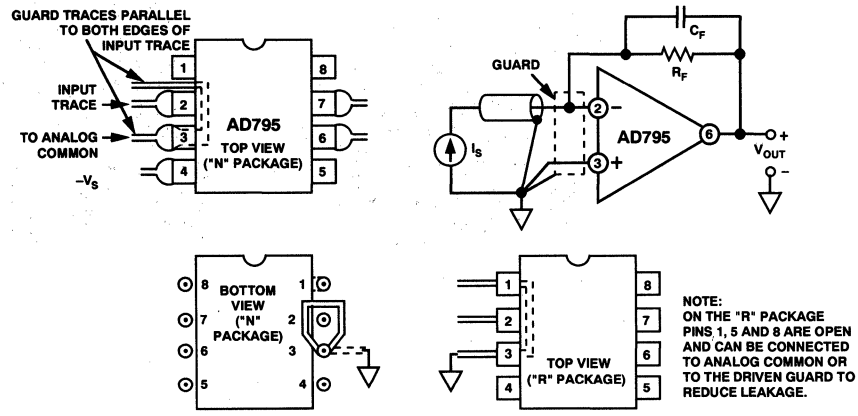

Figure 31. Guarding Scheme–Inverter

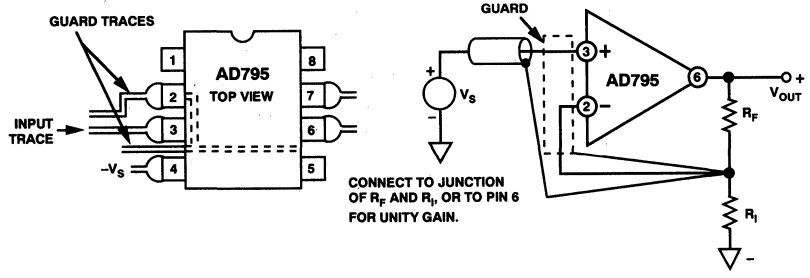

Figure 32. Guard Scheme–Follower

Leakage through the bulk of the circuit board will still occur with the guarding schemes shown in Figures 31 and 32. Standard "G10" type printed circuit board material may not have high enough volume resistivity to hold leakages at the subpicoampere level particularly under high humidity conditions. One option that eliminates all effects of board resistance is shown in Figure 33. The AD795's sensitive input pin (either Pin 2 when connected as an inverter, or Pin 3 when connected as a follower) is bent up and soldered directly to a Teflon* insulated standoff. Both the signal input and feedback component leads must also be insulated from the circuit board by Teflon standoffs or low-leakage shielded cable.

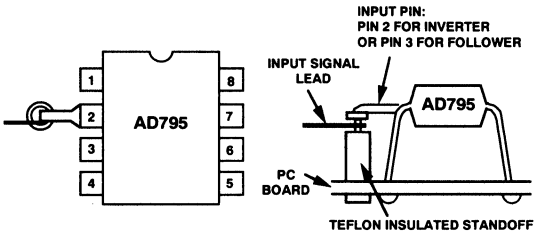

Figure 33. Input Pin to Insulating Standoff

Contaminants such as solder flux on the board's surface and on the amplifier's package can greatly reduce the insulation resistance between the input pin and those traces with supply or signal voltages. Both the package and the board must be kept clean and dry. An effective cleaning procedure is to first swab the surface with high grade isopropyl alcohol, then rinse it with deionized water and, finally, bake it at 100°C for 1 hour. Polypropylene and polystyrene capacitors should not be subjected to the 100°C bake as they will be damaged at temperatures greater than 80°C.

Other guidelines include making the circuit layout as compact as possible and reducing the length of input lines. Keeping circuit board components rigid and minimizing vibration will reduce triboelectric and piezoelectric effects. All precision high impedance circuitry requires shielding from electrical noise and interference. For example, a ground plane should be used under all high value (i.e., greater than 1 MΩ) feedback resistors. In some cases, a shield placed over the resistors, or even the entire amplifier, may be needed to minimize electrical interference originating from other circuits. Referring to the equation in Figure 30, this coupling can take place in either, or both, of two different forms—coupling via time varying fields:

$$\frac{dV}{dT} C_P$$

or by injection of parasitic currents by changes in capacitance due to mechanical vibration:

$$\frac{dCp}{dt} V$$

*Teflon is a registered trademark of E.I. du Pont Co.

Both proper shielding and rigid mechanical mounting of components help minimize error currents from both of these sources.

OFFSET NULLING

The AD795's input offset voltage can be nulled (mini-DIP package only) by using balance Pins 1 and 5, as shown in Figure 34. Nulling the input offset voltage in this fashion will introduce an added input offset voltage drift component of 2.4 μV/°C per millivolt of nulled offset.

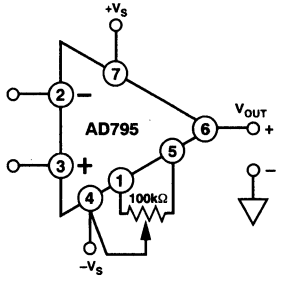

Figure 34. Standard Offset Null Circuit

The circuit in Figure 35 can be used when the amplifier is used as an inverter. This method introduces a small voltage in series with the amplifier's positive input terminal. The amplifier's input offset voltage drift with temperature is not affected. However, variation of the power supply voltages will cause offset shifts.

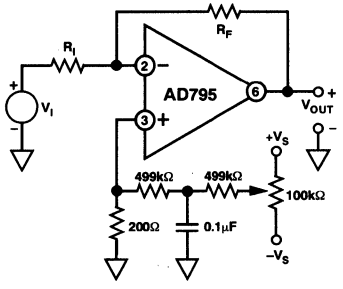

Figure 35. Alternate Offset Null Circuit for Inverter

AC RESPONSE WITH HIGH VALUE SOURCE AND FEEDBACK RESISTANCE

Source and feedback resistances greater than 100 kΩ will magnify the effect of input capacitances (stray and inherent to the AD795) on the ac behavior of the circuit. The effects of common-mode and differential input capacitances should be taken into account since the circuit's bandwidth and stability can be adversely affected.

In a follower, the source resistance, R_S, and input common-mode capacitance, C_S (including capacitance due to board and capacitance inherent to the AD795), form a pole that limits circuit bandwidth to $1/2\ \pi\ R_S C_S$. Figure 36 shows the follower pulse response from a 1 MΩ source resistance with the amplifier's input pin isolated from the board, only the effect of the AD795's input common-mode capacitance is seen.

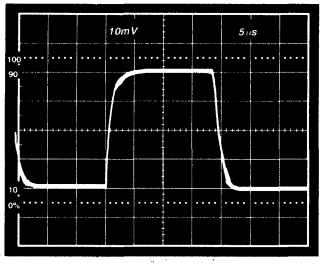

Figure 36. Follower Pulse Response from 1 MΩ Source Resistance

In an inverting configuration, the differential input capacitance forms a pole in the circuit's loop transmission. This can create peaking in the ac response and possible instability. A feedback capacitance can be used to stabilize the circuit. The inverter pulse response with R_F and R_S equal to 1 MΩ, and the input pin isolated from the board appears in Figure 37. Figure 38 shows the response of the same circuit with a 1 pF feedback capacitance. Typical differential input capacitance for the AD795 is 2 pF.

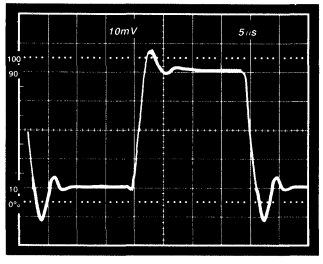

Figure 37. Inverter Pulse Response with 1 MΩ Source and Feedback Resistance

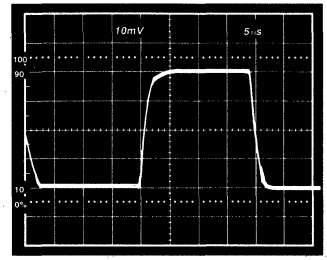

Figure 38. Inverter Pulse Response with 1 MΩ Source and Feedback Resistance, 1 pF Feedback Capacitance

OVERLOAD ISSUES

Driving the amplifier output beyond its linear region causes some sticking; recovery to normal operation is within 2 µs of the input voltage returning within the linear range.

If either input is driven below the negative supply, the amplifier's output will be driven high, causing a phenomenon called phase reversal. Normal operation is resumed within 30 µs of the input voltage returning within the linear range.

Figure 39 shows the AD795's input currents versus differential input voltage. Picoamp level input current is maintained for differential voltages up to several hundred millivolts. This behavior is only important if the AD795 is in an open-loop application where substantial differential voltages are produced.

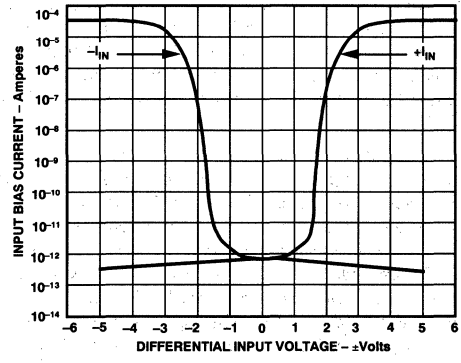

Figure 39. Input Bias Current vs. Differential Input Voltage

INPUT PROTECTION

The AD795 safely handles any input voltage within the supply voltage range. Some applications may subject the input terminals to voltages beyond the supply voltages—in these cases, the following guidelines should be used to maintain the AD795's functionality and performance.

If the inputs are driven more than a 0.5 V below the minus supply, milliamp level currents can be produced through the input terminals. That current should be limited to 10 mA for "transient" overloads (less than 1 second) and 1 mA for continuous overloads, this can be accomplished with a protection resistor in the input terminal (as shown in Figures 40 and 41). The protection resistor's Johnson noise will add to the amplifier's input voltage noise and impact the frequency response.

Driving the input terminals above the positive supply will cause the input current to increase and limit at 40 μA. This condition is maintained until 15 volts above the positive supply—any input voltage within this range does not harm the amplifier. Input voltage above this range causes destructive breakdown and should be avoided.

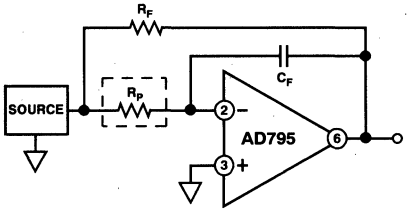

Figure 40. Inverter with Input Current Limit

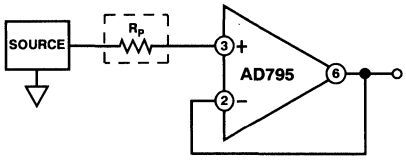

Figure 41. Follower with Input Current Limit

Figure 42 is a schematic of the AD795 as an inverter with an input voltage clamp. Bootstrapping the clamp diodes at the inverting input minimizes the voltage across the clamps and keeps the leakage due to the diodes low. Low leakage diodes (less than 1 pA), such as the FD333's should be used, and should be shielded from light to keep photocurrents from being generated. Even with these precautions, the diodes will measurably increase the input current and capacitance.

In order to achieve the low input bias currents of the AD795, it is not possible to use the same on-chip protection as used in other Analog Devices op amps. This makes the AD795 sensitive to handling and precautions should be taken to minimize ESD exposure whenever possible.

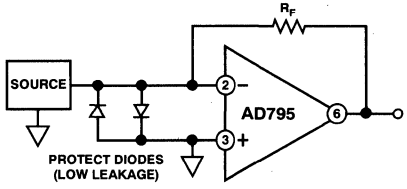

Figure 42. Input Voltage Clamp with Diodes

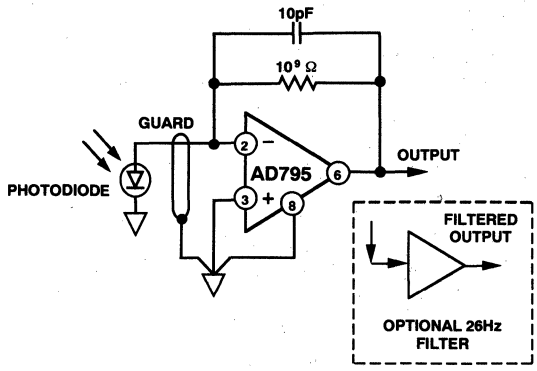

Figure 43. The AD795 Used as a Photodiode Preamplifier

Preamplifier Applications

The low input current and offset voltage levels of the AD795 together with its low voltage noise make this amplifier an excellent choice for preamplifiers used in sensitive photodiode applications. In a typical preamp circuit, shown in Figure 43, the output of the amplifier is equal to:

$$V_{OUT} = I_D\,(Rf) = Rp\,(P)\,Rf$$

where:

I_D = photodiode signal current (Amps)

Rp = photodiode sensitivity (Amp/Watt)

Rf = the value of the feedback resistor, in ohms.

P = light power incident to photodiode surface, in watts.

An equivalent model for a photodiode and its dc error sources is shown in Figure 44. The amplifier's input current, I_B, will contribute an output voltage error which will be proportional to the value of the feedback resistor. The offset voltage error, V_{OS}, will cause a "dark" current error due to the photodiode's finite shunt resistance, Rd. The resulting output voltage error, V_E, is equal to:

$$V_E = (1 + Rf/Rd)\,V_{OS} + Rf\,I_B$$

A shunt resistance on the order of 10^9 ohms is typical for a small photodiode. Resistance Rd is a junction resistance which will typically drop by a factor of two for every 10°C rise in temperature. In the AD795, both the offset voltage and drift are low, this helps minimize these errors.

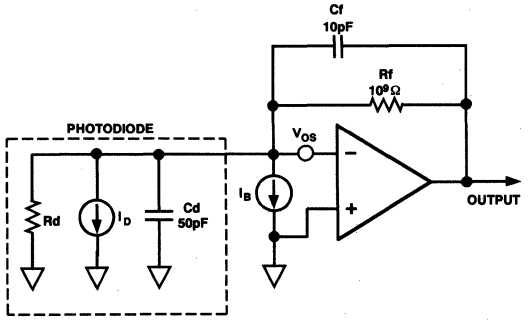

Figure 44. A Photodiode Model Showing DC Error Sources

Minimizing Noise Contributions

The noise level limits the resolution obtainable from any preamplifier. The total output voltage noise divided by the feedback resistance of the op amp defines the minimum detectable signal current. The minimum detectable current divided by the photodiode sensitivity is the minimum detectable light power.

Sources of noise in a typical preamp are shown in Figure 45. The total noise contribution is defined as:

$$\overline{V_{OUT}} = \sqrt{(\overline{i_n^2} + \overline{i_f^2} + \overline{i_s^2})\left(\frac{Rf}{1 + s\,(Cf)\,Rf}\right)^2 + (\overline{en^2})\left(1 + \frac{Rf}{Rd}\left(\frac{1 + s\,(Cd)\,Rd}{1 + s\,(Cf)\,Rf}\right)\right)^2}$$

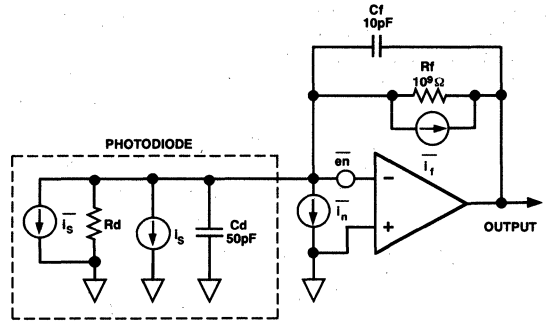

Figure 45. Noise Contributions of Various Sources

Figure 46, a spectral density versus frequency plot of each source's noise contribution, shows that the bandwidth of the amplifier's input voltage noise contribution is much greater than its signal bandwidth. In addition, capacitance at the summing junction results in a "peaking" of noise gain in this configuration. This effect can be substantial when large photodiodes with large shunt capacitances are used. Capacitor Cf sets the signal bandwidth and also limits the peak in the noise gain. Each source's rms or root-sum-square contribution to noise is obtained by integrating the sum of the squares of all the noise sources and then by obtaining the square root of this sum. Minimizing the total area under these curves will optimize the preamplifier's overall noise performance.

An output filter with a passband close to that of the signal can greatly improve the preamplifier's signal to noise ratio. The photodiode preamplifier shown in Figure 45—without a bandpass filter—has a total output noise of 50 μV rms. Using a 26 Hz single pole output filter, the total output noise drops to 23 μV rms, a factor of 2 improvement with no loss in signal bandwidth.

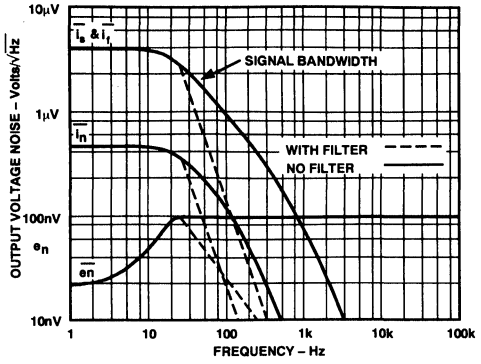

Figure 46. Voltage Noise Spectral Density of the Circuit of Figure 45 with and without an Output Filter

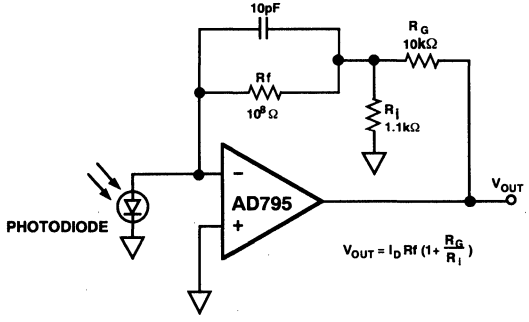

Figure 47. A Photodiode Preamp Employing a "T" Network for Added Gain

Using a "T" Network

A "T" network, shown in Figure 47, can be used to boost the effective transimpedance of an I to V converter, for a given feedback resistor value. However, amplifier noise and offset voltage contributions are also amplified by the "T" network gain. A low noise, low offset voltage amplifier, such as the AD795, is needed for this type of application.

A pH Probe Buffer Amplifier

A typical pH probe requires a buffer amplifier to isolate its 10^6 to 10^9 Ω source resistance from external circuitry. Just such an amplifier is shown in Figure 48. The low input current of the AD795 allows the voltage error produced by the bias current and electrode resistance to be minimal. The use of guarding, shielding, high insulation resistance standoffs, and other such standard methods used to minimize leakage are all needed to maintain the accuracy of this circuit.

The slope of the pH probe transfer function, 50 mV per pH unit at room temperature, has a +3300 ppm/°C temperature coefficient. The buffer of Figure 48 provides an output voltage equal to 1 volt/pH unit. Temperature compensation is provided by resistor RT which is a special temperature compensation resistor, part number Q81, 1 kΩ, 1%, +3500 ppm/°C, available from Tel Labs Inc.

Ultralow Distortion, Ultralow Noise Op Amp

AD797*

FEATURES

Low Noise
- 0.9 nV/√Hz typ (1.2 nV/√Hz max) Input Voltage Noise at 1 kHz
- 50 nV p–p Input Voltage Noise, 0.1 to 10 Hz

Low Distortion
- –120 dB Total Harmonic Distortion at 20 kHz

Excellent AC Characteristics
- 800 ns Settling Time to 16 Bits (10 V Step)
- 110 MHz Gain Bandwidth (G = 1000)
- 8 MHz Bandwidth (G = 10)
- 280 kHz Full Power Bandwidth at 20 V p–p
- 20 V/μs Slew Rate

Excellent DC Precision
- 80 μV max Input Offset Voltage
- 1.0 μV/°C V_{OS} Drift

Specified for ±5 V and ±15 V Power Supplies

High Output Drive Current of 50 mA

APPLICATIONS

Professional Audio Preamplifiers

IR, CCD, and Sonar Imaging Systems

Spectrum Analyzers

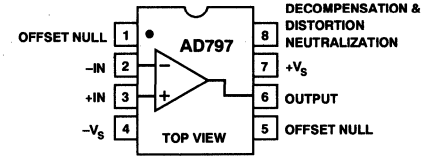
Ultrasound Preamplifiers

Seismic Detectors

ΣΔ ADC/DAC Buffers

CONNECTION DIAGRAM

8-Pin Plastic Mini-DIP (N), Cerdip (Q) and SOIC (R) Packages



PRODUCT DESCRIPTION

The AD797 is a very low noise, low distortion operational amplifier ideal for use as a preamplifier. The low noise of 0.9 nV/√Hz and low total harmonic distortion of –120 dB at audio bandwidths give the AD797 the wide dynamic range necessary for preamps in microphones and mixing consoles. Furthermore, the AD797's excellent slew rate of 20 V/μs and 110 MHz gain bandwidth make it highly suitable for low frequency ultrasound applications.

The AD797 is also useful in IR and Sonar Imaging applications where the widest dynamic range is necessary. The low distortion and 16-bit settling time of the AD797 make it ideal for buffering the inputs to ΣΔ ADCs or the outputs of high resolution DACs especially when they are used in critical applications such as seismic detection and spectrum analyzers. Key features such as a 50 mA output current drive and the specified power supply voltage range of ±5 to ±15 volts make the AD797 an excellent general purpose amplifier.

NOTES

[1]Stresses above those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. This is a stress rating only, and functional operation of the device at these or any other conditions above those indicated in the operational section of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.

[2]Internal Power Dissipation:
8-Pin SOIC = 0.9 Watts − $(T_A - 25°C)/\theta_{JA}$
8-Pin Plastic DIP and Cerdip = 1.3 Watts − $(T_A - 25°C)/\theta_{JA}$
Thermal Characteristics
8-Pin Plastic DIP Package: θ_{JA} = 95°C/W
8-Pin Cerdip Package: θ_{JA} = 110°C/W
8-Pin Small Outline Package: θ_{JA} = 155°C/W

[3]The AD797's inputs are protected by back-to-back diodes. To achieve low noise, internal current limiting resistors are not incorporated into the design of this amplifier. If the differential input voltage exceeds ±0.7 V, the input current should be limited to less than 25 mA by series protection resistors. Note, however, that this will degrade the low noise performance of the device.

ESD SUSCEPTIBILITY

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 volts, which readily accumulate on the human body and on test equipment, can discharge without detection. Although the AD797 features proprietary ESD protection circuitry, permanent damage may still occur on these devices if they are subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid any performance degradation or loss of functionality.

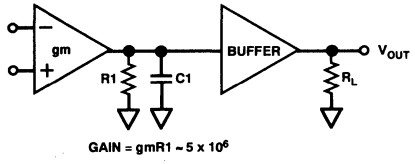
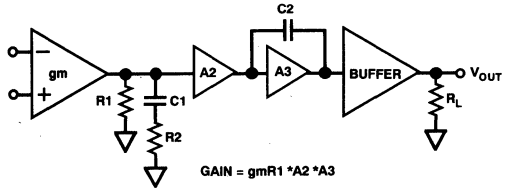
THEORY OF OPERATION

The new architecture of the AD797 was developed to overcome inherent limitations in previous amplifier designs. Previous precision amplifiers used three stages to ensure high open-loop gain, Figure 27b, at the expense of additional frequency compensation components. Slew rate and settling performance are usually compromised, and dynamic performance is not adequate beyond audio frequencies. As can be seen in Figure 27b, the first stage gain is rolled off at high frequencies by the compensation network. Second stage noise and distortion will then appear at the input and degrade performance. The AD797 on the other hand, uses a single ultrahigh gain stage to achieve dc as well as dynamic precision. As shown in the simplified schematic (Figure 28), nodes A, B, and C all track in voltage forcing the operating points of all pairs of devices in the signal path to match. By exploiting the inherent matching of devices fabricated on the same IC chip, high open-loop gain, CMRR, PSRR, and low V_{OS} are all guaranteed by pairwise device *matching* (i.e., NPN to NPN & PNP to PNP), and not absolute parameters such as beta and early voltage.



a.



b.

Figure 27. Model of AD797 vs. That of a Typical Three-Stage Amplifier

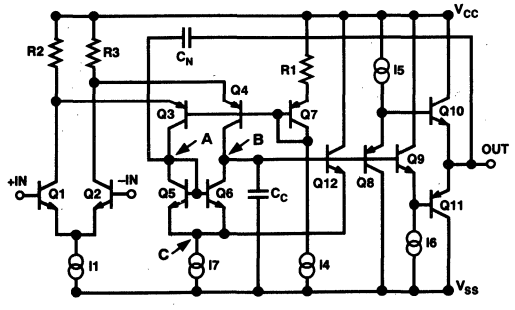


Figure 28. AD797 Simplified Schematic

This matching benefits not just dc precision but since it holds up dynamically, both distortion and settling time are also reduced. This single stage has a voltage gain of $>5 \times 10^6$ and V_{OS} <80 μV, while at the same time providing THD + noise of less than −120 dB and true 16 bit settling in less than 800 ns. The elimination of second stage noise effects has the additional benefit of making the low noise of the AD797 (<0.9 nV/$\sqrt{Hz}$) extend to beyond 1 MHz. This means new levels of performance for sampled data and imaging systems. All of this performance as well as load drive in excess of 30 mA are made possible by Analog Devices' advanced Complementary Bipolar (CB) process.

Another unique feature of this circuit is that the addition of a single capacitor, C_N (Figure 28), enables cancellation of distortion due to the output stage. This can best be explained by referring to a simplified representation of the AD797 using idealized blocks for the different circuit elements (Figure 29).

A single equation yields the open-loop transfer function of this amplifier, solving it (at Node B) yields:

$$\frac{V_O}{V_{IN}} = \frac{gm}{\frac{C_N}{A} j\omega - C_N j\omega - \frac{C_C}{A} j\omega}$$

gm = the transconductance of Q1 and Q2
A = the gain of the output stage, (~1)
V_O = voltage at the output
V_{IN} = differential input voltage

When C_N is equal to C_C this gives the ideal single pole op amp response:

$$\frac{V_O}{V_{IN}} = \frac{gm}{j\omega C}$$

The terms in A, which include the properties of the output stage such as output impedance and distortion, cancel by simple subtraction, and therefore the distortion cancellation does not affect the stability or frequency response of the amplifier. With only 500 μA of output stage bias the AD797 delivers a 1 kHz sine wave into 600 Ω at 7 V rms with only 1 ppm of distortion.

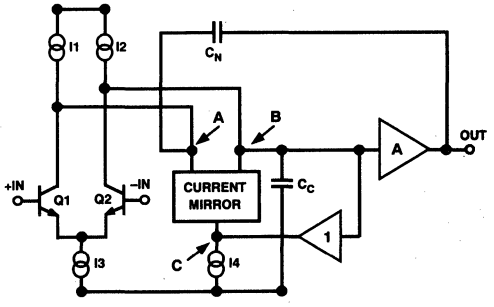

Figure 29. AD797 Block Diagram

NOISE AND SOURCE IMPEDANCE CONSIDERATIONS

The AD797's ultralow voltage noise of 0.9 nV$\sqrt{\text{Hz}}$ is achieved with special input transistors running at nearly 1 mA of collector current. It is important then to consider the total input referred noise (e_N*total*), which includes contributions from voltage noise (e_N), current noise (i_N), and resistor noise ($\sqrt{4\ kTr_S}$).

$$e_N total = [e_N^2 + 4\ kTr_S + 4\ (i_N r_S)^2]^{1/2} \quad \text{Equation 1}$$

where r_S = total input source resistance.

This equation is plotted for the AD797 in Figure 30. Since optimum dc performance is obtained with matched source resistances, this case is considered even though it is clear from Equation 1 that eliminating the balancing source resistance will lower the total noise by reducing the total r_S by a factor of two.

At very low source resistance (r_S <50 Ω), the amplifiers' voltage noise dominates. As source resistance increases the Johnson noise of r_S dominates until at higher resistances (r_S >2 kΩ) the current noise component is larger than the resistor noise.

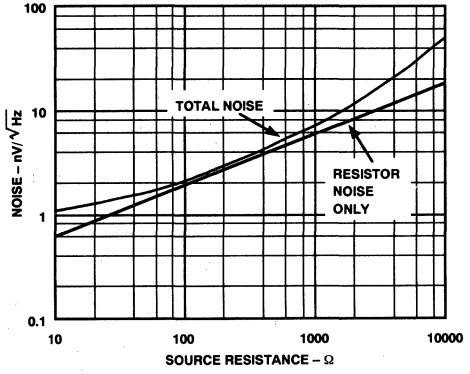

Figure 30. Noise vs. Source Resistance

The AD797 is the optimum choice for low noise performance provided the source resistance is kept <1 kΩ. At higher values of source resistance, optimum performance with respect to noise alone is obtained with other amplifiers from Analog Devices (see Table I).

Table I. Recommended Amplifiers for Different Source Impedances

r_S, ohms	Recommended Amplifier
0 to <1 k	AD797
1 k to <10 k	AD707, AD743/AD745, OP-27/OP-37, OP-07
10 k to <100 k	AD705, AD743/AD745, OP-07
>100 k	AD548, AD549, AD645, AD711, AD743/AD745

LOW FREQUENCY NOISE

Analog Devices specifies low frequency noise as a peak to peak (p–p) quantity in a 0.1 Hz to 10 Hz bandwidth. Several techniques can be used to make this measurement. The usual technique involves amplifying, filtering, and measuring the amplifiers noise for a predetermined test time. The noise bandwidth of the filter is corrected for and the test time is carefully controlled since the measurement time acts as an additional low frequency roll-off.

The plot in Figure 4 was made using a slightly different technique. Here an FFT based instrument (Figure 31) is used to generate a 10 Hz "brickwall" filter. A low frequency pole at 0.1 Hz is generated with an external ac coupling capacitor, the instrument being dc coupled.

Several precautions are necessary to get optimum low frequency noise performance:

1. Care must be used to account for the effects of r_S, even a 10 Ω resistor has 0.4 nV$\sqrt{\text{Hz}}$ of noise (an error of 9% when root sum squared with 0.9 nV$\sqrt{\text{Hz}}$).
2. The test set up must be fully warmed up to prevent e_{OS} drift from erroneously contributing to input noise.
3. Circuitry must be shielded from air currents. Heat flow out of the package through its leads creates the opportunity for a thermo-electric potential at every junction of different metals. Selective heating and cooling of these by random air currents will appear as 1/f noise and obscure the true device noise.
4. The results must be interpreted using valid statistical techniques.

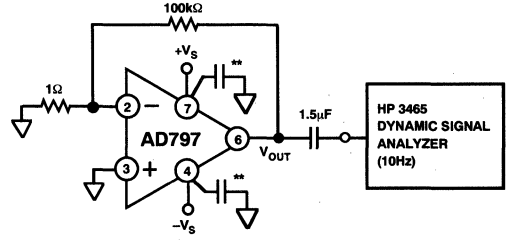

Figure 31. Test Setup for Measuring 0.1 Hz to 10 Hz Noise

WIDEBAND NOISE

The AD797, due to its single stage design, has the property that its noise is flat over frequencies from less than 10 Hz to beyond 1 MHz. This is not true of most dc precision amplifiers where second stage noise contributes to input referred noise beyond the audio frequency range. The AD797 offers new levels of performance in wideband imaging applications. In sampled data systems, where aliasing of out of band noise into the signal band is a problem, the AD797 will out perform all previously available IC op amps.

BYPASSING CONSIDERATIONS

To take full advantage of the very wide bandwidth and dynamic range capabilities of the AD797 requires some precautions. First, multiple bypassing is recommended in any precision application. A 1.0 μF–4.7 μF tantalum in parallel with 0.1 μF ceramic bypass capacitors are sufficient in most applications. When driving heavy loads a larger demand is placed on the supply bypassing. In this case selective use of larger values of tantalum capacitors and damping of their lead inductance with small value (1.1 Ω to 4.7 Ω) carbon resistors can be an improvement. Figure 32 summarizes bypassing recommendations. The symbol (**) is used throughout this data sheet to represent the parallel combination of a 0.1 μF and a 4.7 μF capacitor.

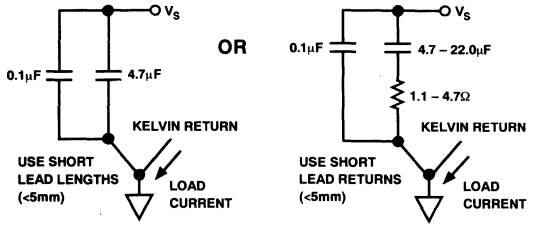

Figure 32. Recommended Power Supply Bypassing

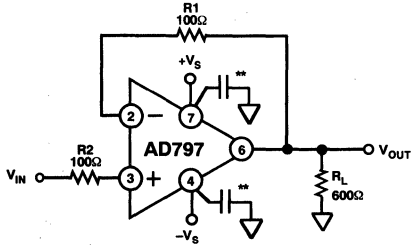
THE NONINVERTING CONFIGURATION

Ultralow noise requires very low values of r_{BB}' (the internal parasitic resistance) for the input transistors (≈ 6 Ω). This implies very little damping of input and output reactive interactions. With the AD797, additional input series damping is required for stability with direct input to output feedback. A 100 Ω resistor in the inverting input (Figure 33) is sufficient; the 100 Ω balancing resistor (R2) is recommended, but is not required for stability. The noise penalty is minimal (e_N*total* ≈2.1 nV$\sqrt{\text{Hz}}$), which is usually insignificant. Best response flatness is obtained with the addition of a small capacitor (C_L <33 pF) in parallel with the 100 Ω resistor (Figure 34). The input source resistance and capacitance will also affect the response slightly and experimentation may be necessary for best results.



** USE POWER SUPPLY BYPASSING SHOWN IN FIGURE 32.

Figure 33. Voltage Follower Connection

Low noise preamplification is usually done in the noninverting mode (Figure 35). For lowest noise the equivalent resistance of the feedback network should be as low as possible. The 30 mA minimum drive current of the AD797 makes it easier to achieve this. The feedback resistors can be made as low as possible with due consideration to load drive and power consumption. Table II gives some representative values for the AD797 as a low noise follower. Operation on 5 volt supplies allows the use of a 100 Ω or less feedback network (R1+ R2). Since the AD797 shows no unusual behavior when operating near its maximum rated current, it is suitable for driving the AD600/AD602 (Figure 47) while preserving their low noise performance.

Optimum flatness and stability at noise gains >1 sometimes requires a small capacitor (C_L) connected across the feedback resistor (R1, Figure 35). Table II includes recommended values of C_L for several gains. In general, when R2 is greater than 100 Ω and C_L is greater than 33 pF, a 100 Ω resistor should be placed in series with C_L. Source resistance matching is assumed, and the AD797 should never be operated with unbalanced source resistance >200 kΩ/G.

Figure 35. Low Noise Preamplifier

Table II. Values for Follower with Gain Circuit

Gain	R1	R2	C_L	Noise (Excluding r_S)
2	1 kΩ	1 kΩ	≈20 pF	3.0 nV$\sqrt{\text{Hz}}$
2	300 Ω	300 Ω	≈10pF	1.8 nV$\sqrt{\text{Hz}}$
10	33.2 Ω	300 Ω	≈5 pF	1.2 nV$\sqrt{\text{Hz}}$
20	16.5 Ω	316 Ω		1.0 nV$\sqrt{\text{Hz}}$
>35	10 Ω	(G–1) 10 Ω		0.98 nV$\sqrt{\text{Hz}}$

The I-to-V converter is a special case of the follower configuration. When the AD797 is used in an I-to-V converter, for instance as a DAC buffer, the circuit of Figure 36 should be used. The value of C_L depends on the DAC and again, if C_L is

Figure 36. I-to-V Converter Connection

greater than 33 pF a 100 Ω series resistor is required. A by-passed balancing resistor (R_S and C_S) can be included to minimize dc errors.

THE INVERTING CONFIGURATION

The inverting configuration (Figure 37) presents a low input impedance, R1, to the source. For this reason, the goals of both low noise and input buffering are at odds with one another. Nonetheless, the excellent dynamics of the AD797 will make it the preferred choice in many inverting applications, and with careful selection of feedback resistors the noise penalties will be minimal. Some examples are presented in Table II and Figure 37.

−10	150 Ω	1500 Ω	≈5 pF	1.8 nV/√Hz

DRIVING CAPACITIVE LOADS

The capacitive load driving capabilities of the AD797 are displayed in Figure 38. At gains over 10 usually no special precautions are necessary. If more drive is desirable the circuit in Figure 39 should be used. Here a 5000 pF load can be driven cleanly at any noise gain > = 2.

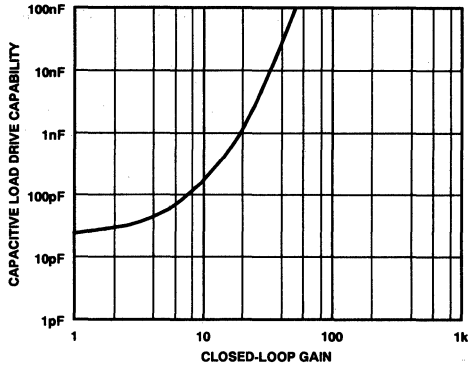

Figure 38. Capacitive Load Drive Capability vs. Closed-Loop Gain

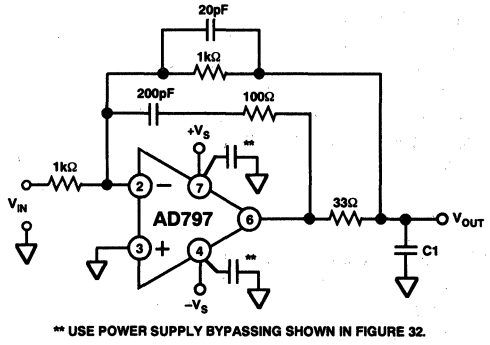

** USE POWER SUPPLY BYPASSING SHOWN IN FIGURE 32.

Figure 39. Recommended Circuit for Driving a High Capacitance Load

SETTLING TIME

The AD797 is unique among ultralow noise amplifiers in that it settles to 16 bits (<150 μV) in less than 800 ns. Measuring this performance presents a challenge. A special test setup (Figure 40) was developed for this purpose. The input signal was obtained from a resonant reed switch pulse generator, available from Tektronix as calibration Fixture No. 067-0608-00. When open, the switch is simply 50 Ω to ground and settling is purely a passive pulse decay and inherently flat. The low repetition rate signal was captured on a digital oscilloscope after being amplified and clamped twice. The selection of plug-in for the oscilloscope was made for minimum overload recovery.

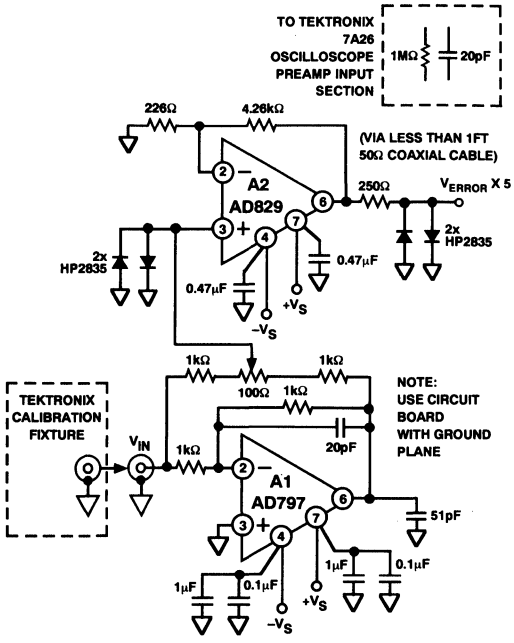

Figure 40. Settling Time Test Circuit

DISTORTION REDUCTION

The AD797 has distortion performance (THD < −120 dB, @ 20 kHz, 3 V rms, RL = 600 Ω) unequaled by most voltage feedback amplifiers.

At higher gains and higher frequencies THD will increase due to reduction in loop gain. However in contrast to most conventional voltage feedback amplifiers the AD797 provides two effective means of reducing distortion, as gain and frequency are increased; cancellation of the output stage's distortion and gain bandwidth enhancement by decompensation. By applying these techniques gain bandwidth can be increased to 450 MHz at G = 1000 and distortion can be held to −100 dB at 20 kHz for G = 100.

The unique design of the AD797 provides for cancellation of the output stage's distortion (patent pending). To achieve this a capacitance equal to the effective compensation capacitance, usually 50 pF, is connected between Pin 8 and the output (C2 in Figure 41). Use of this feature will improve distortion performance when the closed loop gain is more than 10 or when frequencies of interest are greater than 30 kHz.

Bandwidth enhancement via decompensation is achieved by connecting a capacitor from Pin 8 to ground (C1 in Figure 41) effectively subtracting from the value of the internal compensation capacitance (50 pF), yielding a smaller effective compensation capacitance and, therefore, a larger bandwidth. The benefits of this begin at closed loop gains of 100 and up. A maximum value of ≈33 pF at gains of 1000 and up is recommended. At a gain of 1000 the bandwidth is 450 kHz.

Table IV and Figure 42 summarize the performance of the AD797 with distortion cancellation and decompensation.

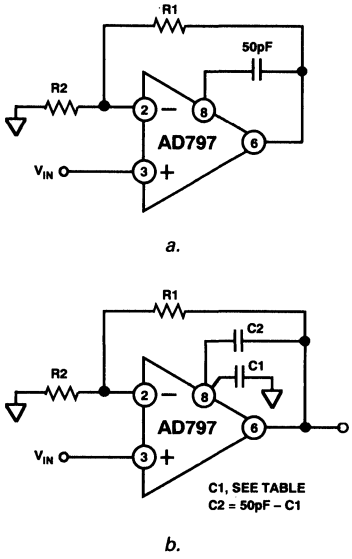

Figure 41. Recommended Connections for Distortion Cancellation and Bandwidth Enhancement

Table IV. Recommended External Compensation

	A/B		A			B		
	R1 Ω	R2 Ω	C1 (pF)	C2 (pF)	3 dB BW	C1 (pF)	C2 (pF)	3 dB BW

G = 100	1 k	10	0	50	1 MHz	15	33	1.5 MHz
G = 1000	10 k	10	0	50	110 kHz	33	15	450 kHz

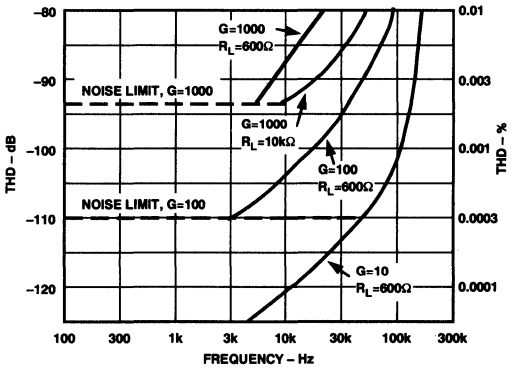

Figure 42. Total Harmonic Distortion (THD) vs. Frequency @ 3 V rms for Figure 41b

Differential Line Receiver

The differential receiver circuit of Figure 43 is useful for many applications from audio to MRI imaging. It allows extraction of a low level signal in the presence of common-mode noise. As shown in Figure 44, the AD797 provides this function with only 9 nV/$\sqrt{\text{Hz}}$ noise at the output. Figure 45 shows the AD797's 20-bit THD performance over the audio band and 16-bit accuracy to 250 kHz.

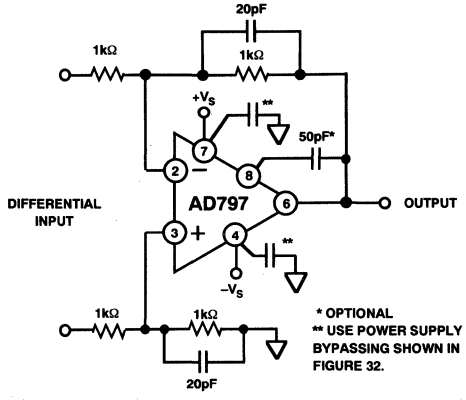

Figure 43. Differential Line Receiver

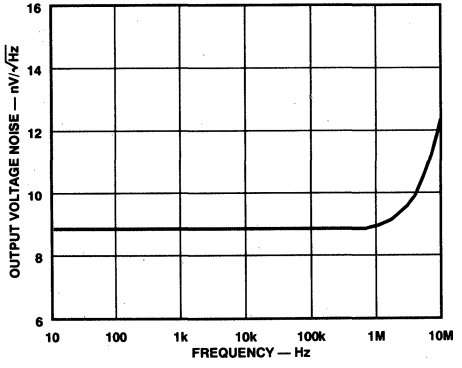

Figure 44. Output Voltage Noise Spectral Density for Differential Line Receiver

A General Purpose ATE/Instrumentation Input/Output Driver

The ultralow noise and distortion of the AD797 may be combined with the wide bandwidth, slew rate, and load drive of a current feedback amplifier to yield a very wide dynamic range general purpose driver. The circuit of Figure 46 combines the AD797 with the AD811 in just such an application. Using the

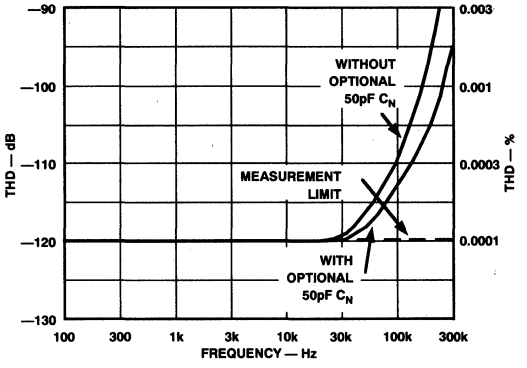

Figure 45. Total Harmonic Distortion (THD) vs. Frequency for Differential Line Receiver

component values shown, this circuit is capable of better than −90 dB THD with a ±5 V, 500 kHz output signal. The circuit is therefore suitable for driving high resolution A/D converters and as an output driver in automatic test equipment (ATE) systems. Using a 100 kHz sine wave, the circuit will drive a 600 Ω load to a level of 7 V rms with less than −109 dB THD, and a 10 kΩ load at less than −117 dB THD.

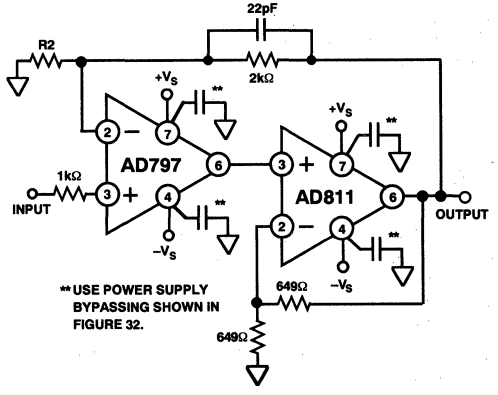

Figure 46. A General Purpose ATE/Instrumentation Input/Output Driver

Ultrasound/Sonar Imaging Preamp

The AD600 variable gain amplifier provides the time controlled gain (TCG) function necessary for very wide dynamic range sonar and low frequency ultrasound applications. Under some circumstances, it is necessary to buffer the input of the AD600 to preserve its low noise performance. To optimize dynamic range this buffer should have at most 6 dB of gain. The combination of low noise and low gain is difficult to achieve. The input buffer circuit shown in Figure 47 provides 1 $nV\sqrt{Hz}$ noise performance at a gain of two (dc to 1 MHz) by using 26.1 Ω resistors in its feedback path. Distortion is only −50 dBc @ 1 MHz at a 2 volt p–p output level and drops rapidly to better than −70 dBc at an output level of 200 mV p–p.

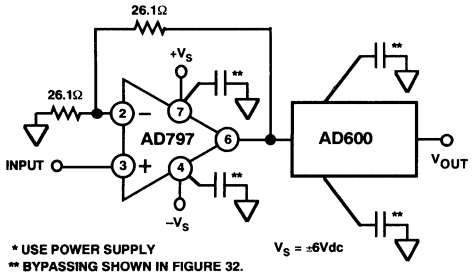

Figure 47. An Ultrasound Preamplifier Circuit

Amorphous (Photodiode) Detector

Large area photodiodes $C_S \geq 500$ pF and certain image detectors (amorphous Si), have optimum performance when used in conjunction with amplifiers with very low voltage rather than very low current noise. Figure 48 shows the AD797 used with an amorphous Si (C_S = 1000 pF) detector. The response is adjusted for flatness using capacitor C_L, while the noise is dominated by voltage noise amplified by the ac noise gain. The 797's excellent input noise performance gives 27 μV rms total noise in a 1 MHz bandwidth, as shown by Figure 49.

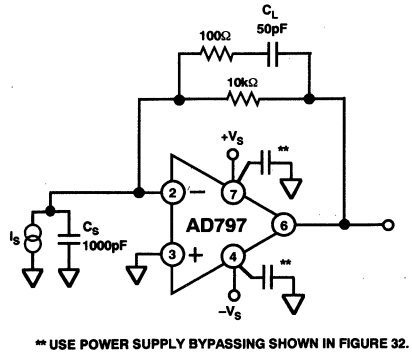

Figure 48. Amorphous Detector Preamp

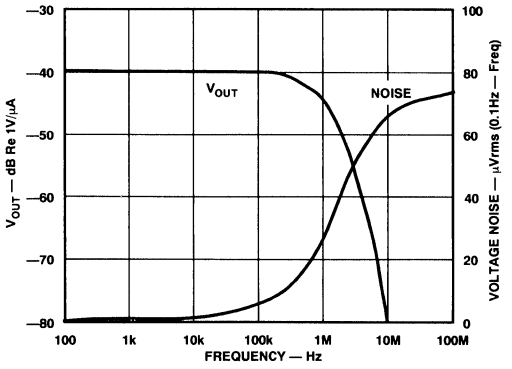

Figure 49. Total Integrated Voltage Noise & V_{OUT} of Amorphous Detector Preamp

Professional Audio Signal Processing—DAC Buffers

The low noise and low distortion of the AD797 make it an ideal choice for professional audio signal processing. An ideal I-to-V converter for a current output DAC would simply be a resistor to ground, were it not for the fact that most DACs do not operate linearly with voltage on their output. Standard practice is to operate an op amp as an I-to-V converter creating a virtual ground at its inverting input. Normally, clock energy and current steps must be absorbed by the op amp's output stage. However, in the configuration of Figure 50, Capacitor C_F shunts high frequency energy to ground, while correctly reproducing the desired output with extremely low THD and IMD.

FEATURES

High Speed
- 80 MHz Bandwidth (3 dB, G = +1)
- 75 MHz Bandwidth (3 dB, G = +2)
- 1000 V/μs Slew Rate
- 50 ns Settling Time to 0.1% (V_O = 10 V Step)

Ideal for Video Applications
- 30 MHz Bandwidth (0.1 dB, G = +2)
- 0.02% Differential Gain
- 0.04° Differential Phase

Low Noise
- 2.9 nV/$\sqrt{Hz}$ Input Voltage Noise
- 13 pA/$\sqrt{Hz}$ Inverting Input Current Noise

Low Power
- 8.0 mA Supply Current max
- 2.1 mA Supply Current (Power-Down Mode)

High Performance Disable Function
- Turn-Off Time 100 ns
- Break Before Make Guaranteed
- Input to Output Isolation of 64 dB (OFF State)

Flexible Operation
- Specified for ±5 V and ±15 V Operation
- ±2.9 V Output Swing Into a 150 Ω Load (V_S = ±5 V)

APPLICATIONS

Professional Video Cameras
Multimedia Systems
NTSC, PAL & SECAM Compatible Systems
Video Line Driver
ADC/DAC Buffer
DC Restoration Circuits

PRODUCT DESCRIPTION

The AD810 is a composite and HDTV compatible, current feedback, video operational amplifier, ideal for use in systems such as multimedia, digital tape recorders and video cameras. The 0.1 dB flatness specification at bandwidth of 30 MHz (G = +2) and the differential gain and phase of 0.02% and 0.04° (NTSC) make the AD810 ideal for any broadcast quality video system. All these specifications are under load conditions of 150 Ω (one 75 Ω back terminated cable).

The AD810 is ideal for power sensitive applications such as video cameras, offering a low power supply current of 8.0 mA max. The disable feature reduces the power supply current to only 2.1 mA, while the amplifier is not in use, to conserve power. Furthermore the AD810 is specified over a power supply range of ±5 V to ±15 V.

The AD810 works well as an ADC or DAC buffer in video systems due to its unity gain bandwidth of 80 MHz. Because the AD810 is a transimpedance amplifier, this bandwidth can be maintained over a wide range of gains while featuring a low noise of 2.9 nV/$\sqrt{Hz}$ for wide dynamic range applications.

NOTES
[1]Stresses above those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. This is a stress rating only and functional operation of the device at these or any other conditions above those indicated in the operational section of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.
[2]8-Pin Plastic Package: θ_{JA} = 90°C/Watt; 8-Pin Cerdip Package: θ_{JA} = 110°C/Watt; 8-Pin SOIC Package: θ_{JA} = 150°C/Watt.

ESD SUSCEPTIBILITY

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 volts, which readily accumulate on the human body and on test equipment, can discharge without detection. Although the AD810 features ESD protection circuitry, permanent damage may still occur on these devices if they are subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid any performance degradation or loss of functionality.

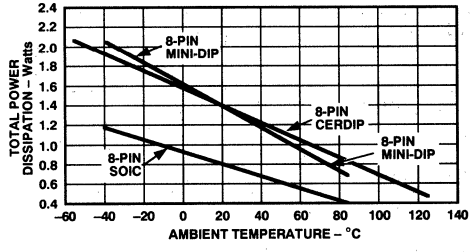
MAXIMUM POWER DISSIPATION

The maximum power that can be safely dissipated by the AD810 is limited by the associated rise in junction temperature. For the plastic packages, the maximum safe junction temperature is 145°C. For the cerdip package, the maximum junction temperature is 175°C. If these maximums are exceeded momentarily, proper circuit operation will be restored as soon as the die



Maximum Power Dissipation vs. Temperature

temperature is reduced. Leaving the device in the "overheated" condition for an extended period can result in device burnout. To ensure proper operation, it is important to observe the derating curves.

While the AD810 is internally short circuit protected, this may not be sufficient to guarantee that the maximum junction temperature is not exceeded under all conditions.

AD810 — Applications

GENERAL DESIGN CONSIDERATIONS

The AD810 is a current feedback amplifier optimized for use in high performance video and data acquisition systems. Since it uses a current feedback architecture, its closed-loop bandwidth depends on the value of the feedback resistor. Table I below contains recommended resistor values for some useful closed-loop gains and supply voltages. As you can see in the table, the closed-loop bandwidth is not a strong function of gain, as it would be for a voltage feedback amp. The recommended resistor values will result in maximum bandwidths with less than 0.1 dB of peaking in the gain vs. frequency response.

The −3 dB bandwidth is also somewhat dependent on the power supply voltage. Lowering the supplies increases the values of internal capacitances, reducing the bandwidth. To compensate for this, smaller values of feedback resistor are sometimes used at lower supply voltages. The characteristic curves illustrate that bandwidths of over 100 MHz on 30 V total and over 50 MHz on 5 V total supplies can be achieved.

Table I. −3 dB Bandwidth vs. Closed-Loop Gain and Resistance Values (R_L = 150 Ω)

V_S = ±15 V Closed-Loop Gain	R_{FB}	R_G	−3 dB BW (MHz)
+1	1 kΩ		80
+2	715 Ω	715 Ω	75
+10	270 Ω	30 Ω	65
−1	681 Ω	681 Ω	70
−10	249 Ω	24.9 Ω	65
V_S = ±5 V Closed-Loop Gain	**R_{FB}**	**R_G**	**−3 dB BW (MHz)**
+1	910 Ω		50
+2	715 Ω	715 Ω	50
+10	270 Ω	30 Ω	50
−1	620 Ω	620 Ω	55
−10	249 Ω	24.9 Ω	50

ACHIEVING VERY FLAT GAIN RESPONSE AT HIGH FREQUENCY

Achieving and maintaining gain flatness of better than 0.1 dB above 10 MHz is not difficult if the recommended resistor values are used. The following issues should be considered to ensure consistently excellent results.

CHOICE OF FEEDBACK AND GAIN RESISTOR

Because the 3 dB bandwidth depends on the feedback resistor, the fine scale flatness will, to some extent, vary with feedback resistor tolerance. It is recommended that resistors with a 1% tolerance be used if it is desired to maintain exceptional flatness over a wide range of production lots.

PRINTED CIRCUIT BOARD LAYOUT

As with all wideband amplifiers, PC board parasitics can affect the overall close-loop performance. Most important are stray capacitances at the output and inverting input nodes. (An added capacitance of 2 pF between the inverting input and ground will add about 0.2 dB of peaking in the gain of 2 response, and increase the bandwidth to 105 MHz.) A space (3/16″ is plenty) should be left around the signal lines to minimize coupling. Also, signal lines connecting the feedback and gain resistors should be short enough so that their associated inductance does not cause high frequency gain errors. Line lengths less than 1/4″ are recommended.

QUALITY OF COAX CABLE

Optimum flatness when driving a coax cable is possible only when the driven cable is terminated at each end with a resistor matching its characteristic impedance. If coax were ideal, then the resulting flatness would not be affected by the length of the cable. While outstanding results can be achieved using inexpensive cables, some variation in flatness due to varying cable lengths is to be expected.

POWER SUPPLY BYPASSING

Adequate power supply bypassing can be critical when optimizing the performance of a high frequency circuit. Inductance in the power supply leads can contribute to resonant circuits that produce peaking in the amplifier's response. In addition, if large current transients must be delivered to the load, then bypass capacitors (typically greater than 1 μF) will be required to provide the best settling time and lowest distortion. Although the recommended 0.1 μF power supply bypass capacitors will be sufficient in most applications, more elaborate bypassing (such as using two paralleled capacitors) may be required in some cases.

POWER SUPPLY OPERATING RANGE

The AD810 will operate with supplies from ±18 V down to about ±2.5 V. On ±2.5 V the low distortion output voltage swing will be better than 1 V peak to peak. Single supply operation can be realized with excellent results by arranging for the input common-mode voltage to be biased at the supply midpoint.

OFFSET NULLING

A 10 kΩ pot connected between Pins 1 and 5, with its wiper connected to V+, can be used to trim out the inverting input current (with about ±20 μA of range). For closed-loop gains above about 5, this may not be sufficient to trim the output offset voltage to zero. Tie the pot's wiper to ground through a large value resistor (50 kΩ for ±5 V supplies, 150 kΩ for ±15 V supplies) to trim the output to zero at high closed-loop gains.

CAPACITIVE LOADS

When used with the appropriate feedback resistor, the AD810 can drive capacitive loads exceeding 1000 pF directly without oscillation. By using the curves in Figure 45 to chose the resistor value, less than 1 dB of peaking can easily be achieved without sacrificing much bandwidth. Note that the curves were generated for the case of a 10 kΩ load resistor, for smaller load resistances, the peaking will be less than indicated by Figure 45.

Another method of compensating for large load capacitances is to insert a resistor in series with the loop output as shown in Figure 43. In most cases, less than 50 Ω is all that is needed to achieve an extremely flat gain response.

Figures 44 to 46 illustrate the outstanding performance that can be achieved when driving a 1000 pF capacitor.

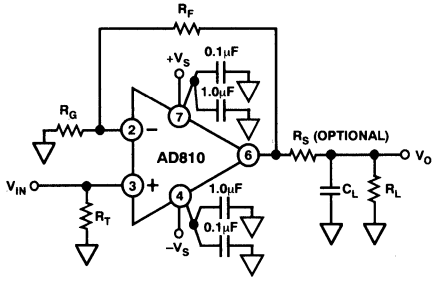

Figure 43. Circuit Options for Driving a Large Capacitive Load

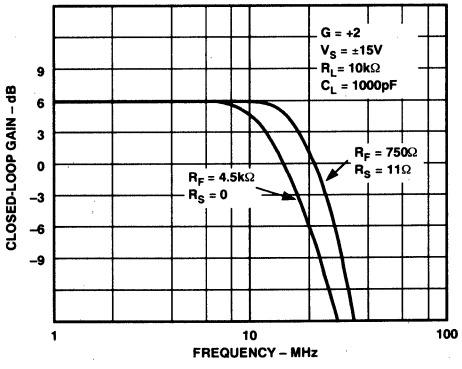

Figure 44. Performance Comparison of Two Methods for Driving a Large Capacitive Load

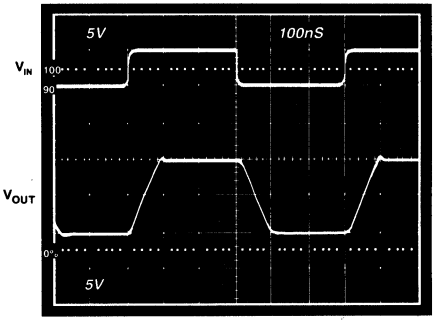

Figure 46. AD810 Driving a 1000 pF Load, Gain = +2, R_F = 750 Ω, R_S = 11 Ω, R_L = 10 kΩ

DISABLE MODE

By pulling the voltage on Pin 8 to common (0 V), the AD810 can be put into a disabled state. In this condition, the supply current drops to less than 2.8 mA, the output becomes a high impedance, and there is a high level of isolation from input to output. In the case of a line driver for example, the output impedance will be about the same as for a 1.5 kΩ resistor (the feedback plus gain resistors) in parallel with a 13 pF capacitor (due to the output) and the input to output isolation will be better than 65 dB at 1 MHz.

Leaving the disable pin disconnected (floating) will leave the AD810 operational in the enabled state.

In cases where the amplifier is driving a high impedance load, the input to output isolation will decrease significantly if the input signal is greater than about 1.2 V peak to peak. The isolation can be restored back to the 65 dB level by adding a dummy load (say 150 Ω) at the amplifier output. This will attenuate the feedthrough signal. (This is not an issue for multiplexer applications where the outputs of multiple AD810s are tied together as long as at least one channel is in the ON state.) The input impedance of the disable pin is about 35 kΩ in parallel with a few pF. When grounded, about 50 μA flows out of the disable

the disable pin for ±5 V supplies. If driven by complementary output CMOS logic (such as the 74HC04), the disable time (until the output goes high impedance) is about 100 ns and the enable time (to low impedance output) is about 170 ns on ±5 V supplies. The enable time can be extended to about 750 ns by using open drain logic such as the 74HC05.

When operated on ±15 V supplies, the AD810 disable pin may be driven by open drain logic such as the 74C906. In this case, adding a 10 kΩ pull-up resistor from the disable pin to the plus supply will decrease the enable time to about 150 ns. If there is a nonzero voltage present on the amplifier's output at the time it is switched to the disabled state, some additional decay time will be required for the output voltage to relax to zero. The total time for the output to go to zero will generally be about 250 ns and is somewhat dependent on the load impedance.

OPERATION AS A VIDEO LINE DRIVER

The AD810 is designed to offer outstanding performance at closed-loop gains of one or greater. At a gain of 2, the AD810 makes an excellent video line driver. The low differential gain and phase errors and wide −0.1 dB bandwidth are nearly independent of supply voltage and load (as seen in Figures 49 and 50).

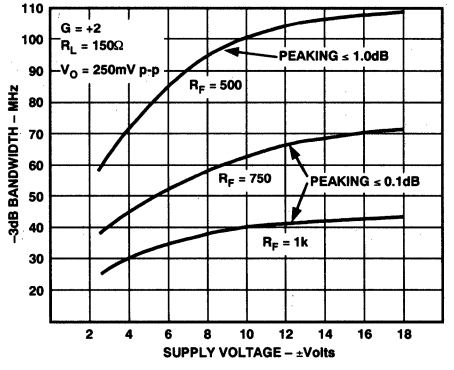

Figure 51. −3 dB Bandwidth vs. Supply Voltage, Gain = +2, R_L = 150 Ω

2:1 VIDEO MULTIPLEXER

The outputs of two AD810s can be wired together to form a 2:1 mux without degrading the flatness of the gain response. Figure 54 shows a recommended configuration which results in −0.1 dB bandwidth of 20 MHz and OFF channel isolation of 77 dB at 10 MHz on ±5 V supplies. The time to switch between channels is about 0.75 μs when the disable pins are driven by open drain output logic. Adding pull-up resistors to the logic outputs or using complementary output logic (such as the 74HC04) reduces the switching time to about 180 ns. The switching time is only slightly affected by the signal level.

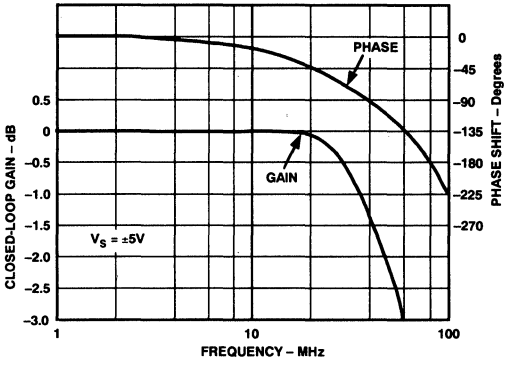

Figure 55. 2:1 Mux ON Channel Gain and Phase vs. Frequency

9

N:1 MULTIPLEXER

A multiplexer of arbitrary size can be formed by combining the desired number of AD810s together with the appropriate selection logic. The schematic in Figure 58 shows a recommendation for a 4:1 mux which may be useful for driving a high impedance such as the input to a video A/D converter (such as the AD773). The output series resistors effectively compensate for the combined output capacitance of the OFF channels plus the input capacitance of the A/D while maintaining wide bandwidth. In the case illustrated, the −0.1 dB bandwidth is about 20 MHz with no peaking. Switching time and OFF channel isolation (for the 4:1 mux) are about 250 ns and 60 dB at 10 MHz, respectively.

ANALOG DEVICES

High Performance Video Op Amp

AD811

FEATURES

High Speed
- 140 MHz Bandwidth (3 dB, G = +1)
- 120 MHz Bandwidth (3 dB, G = +2)
- 35 MHz Bandwidth (0.1 dB, G = +2)
- 2500 V/μs Slew Rate
- 25 ns Settling Time to 0.1% (For a 2 V Step)
- 65 ns Settling Time to 0.01% (For a 10 V Step)

Excellent Video Performance (R_L = 150 Ω)
- 0.01% Differential Gain, 0.01° Differential Phase
- Voltage Noise of 1.9 nV/√Hz

Low Distortion: THD = −74 dB @ 10 MHz

Excellent DC Precision
- 3 mV max Input Offset Voltage

Flexible Operation
- Specified for ±5 V and ±15 V Operation
- ±2.3 V Output Swing into a 75 Ω Load (V_S = ±5 V)

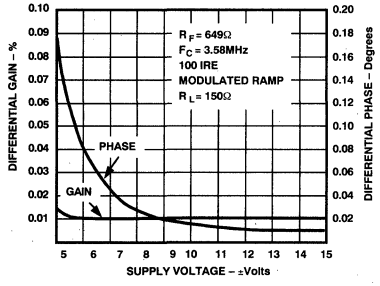
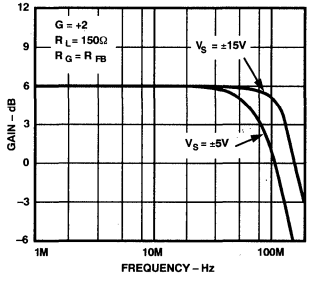
PRODUCT DESCRIPTION

The AD811 is a wideband current-feedback operational amplifier, optimized for broadcast quality video systems. The −3 dB bandwidth of 120 MHz at a gain of +2 and differential gain and phase of 0.01% and 0.01° (R_L = 150 Ω) make the AD811 an excellent choice for all video systems. The AD811 is designed to meet a stringent 0.1 dB gain flatness specification to a bandwidth of 35 MHz (G = +2) in addition to the low differential gain and phase errors. This performance is achieved whether driving one or two back terminated 75 Ω cables, with a low power supply current of 16.5 mA. Furthermore, the AD811 is specified over a power supply range of ±4.5 V to ±18 V.

The AD811 is also excellent for pulsed applications where transient response is critical. It can achieve a maximum slew rate of greater than 2500 V/μs with a settling time of less than 25 ns to 0.1% on a 2 volt step and 65 ns to 0.01% on a 10 volt step.

The AD811 is ideal as an ADC or DAC buffer in data acquisition systems due to its low distortion up to 10 MHz and its wide unity gain bandwidth. Because the AD811 is a current feedback amplifier, this bandwidth can be maintained over a wide range of gains. The AD811 also offers low voltage and current noise of 1.9 nV/√Hz and 20 pA/√Hz, respectively, and excellent dc accuracy for wide dynamic range applications.





This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

MAXIMUM POWER DISSIPATION

The maximum power that can be safely dissipated by the AD811 is limited by the associated rise in junction temperature. For the plastic packages, the maximum safe junction temperature is 145°C. For the cerdip and LCC packages, the maximum junction temperature is 175°C. If these maximums are exceeded momentarily, proper circuit operation will be restored as soon as the die temperature is reduced. Leaving the device in the "overheated" condition for an extended period can result in device burnout. To ensure proper operation, it is important to observe the derating curves in Figures 17 and 18.

While the AD811 is internally short circuit protected, this may not be sufficient to guarantee that the maximum junction temperature is not exceeded under all conditions. One important example is when the amplifier is driving a reverse terminated 75 Ω cable and the cable's far end is shorted to a power supply. With power supplies of ±12 volts (or less) at an ambient temperature of +25°C or less, if the cable is shorted to a supply rail, then the amplifier will not be destroyed, even if this condition persists for an extended period.

ESD SUSCEPTIBILITY

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 volts, which readily accumulate on the human body and on test equipment, can discharge without detection. Although the AD811 features proprietary ESD protection circuitry, permanent damage may still occur on these devices if they are subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid any performance degradation or loss of functionality.

FEATURES

Two Video Amplifiers in One 8-Pin SOIC Package
Optimized for Driving Cables in Video Systems
Excellent Video Specifications (R_L = 150 Ω):
- **Gain Flatness 0.1 dB to 40 MHz**
- **0.02% Differential Gain Error**
- **0.02° Differential Phase Error**

Low Power
- **Operates on Single +3 V Supply**
- **5.5 mA/Amplifier Max Power Supply Current**

High Speed
- **145 MHz Unity Gain Bandwidth (3 dB)**
- **1600 V/μs Slew Rate**

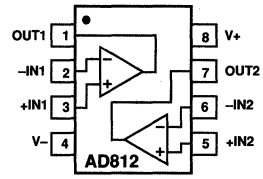
Easy to Use
- **50 mA Output Current**
- **Output Swing to 1 V of Rails (150 Ω Load)**

APPLICATIONS

Video Line Driver
Professional Cameras
Video Switchers
Special Effects

PIN CONFIGURATION

8-Pin Plastic Mini-DIP & SOIC

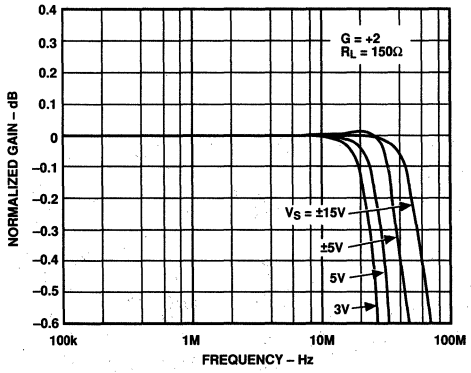


PRODUCT DESCRIPTION

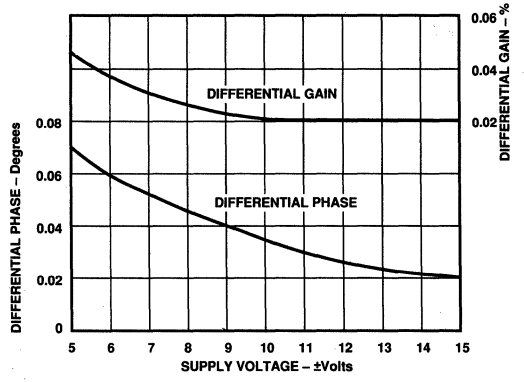
The AD812 is a low power, single supply, dual video amplifier. Each of the amplifiers have 50 mA of output current and are optimized for driving one back terminated video load (150 Ω) each. Each amplifier is a current feedback amplifier and features gain flatness of 0.1 dB to 40 MHz while offering differential gain and phase error of 0.02% and 0.02°. This makes the AD812 ideal for professional video electronics such as cameras and video switchers.

The AD812 offers low power of 4.0 mA per amplifier max (V_S = +5 V) and can run on a single +3 V power supply. The outputs of each amplifier swing to within one volt of either supply rail to easily accommodate video signals of 1 Vp-p. Also, at gains of +2 the AD812 can swing 3 V p-p on a single +5 V power supply. All this is offered in a small 8-pin plastic DIP or 8-pin SOIC package. These features make this dual amplifier ideal for portable and battery powered applications where size and power is critical.

The outstanding bandwidth of 145 MHz along with 1600 V/μs of slew rate make the AD812 useful in many general purpose high speed applications where a single +5 V or dual power supplies up to ±15 V are available. The AD812 is available in the industrial temperature range of –40°C to +85°C.



Fine-Scale Gain Flatness vs. Frequency, Gain = +2, R_L = 150 Ω



Differential Gain and Phase vs. Supply Voltage, Gain = +2, R_L = 150 Ω

SPECIFICATIONS

Dual Supply (@ T_A = +25°C, R_L = 150 Ω, unless otherwise noted)

NOTES
[1]Slew rate measurement is based on 10% to 90% rise time in the specified closed-loop gain.
[2]Single supply differential gain and phase are measured with the ac coupled circuit of Figure 50.
Specifications subject to change without notice.

ABSOLUTE MAXIMUM RATINGS[1]

Supply Voltage ..... ±18 V
Internal Power Dissipation[2]
Plastic (N) ..... 1.3 Watts
Small Outline (R) ..... 0.9 Watts
Input Voltage (Common Mode) ..... $\pm V_S$
Differential Input Voltage ..... ±1.2 V
Output Short Circuit Duration
..... Observe Power Derating Curves
Storage Temperature Range N, R ..... –65°C to +125°C
Operating Temperature Range ..... –40°C to +85°C
Lead Temperature Range (Soldering 10 seconds) .... +300°C

NOTES
[1]Stresses above those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. This is a stress rating only and functional operation of the device at these or any other conditions above those indicated in the operational section of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.
[2]Specification is for device in free air: 8-Pin Plastic Package: θ_{JA} = 90°C/Watt; 8-Pin SOIC Package: θ_{JA} = 140°C/Watt.

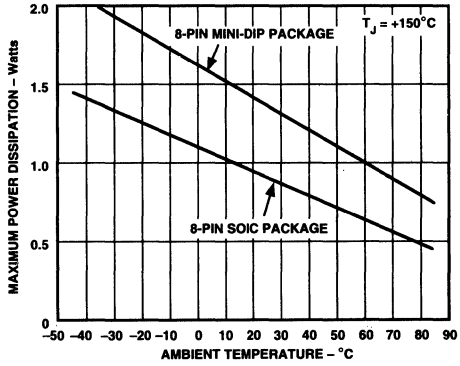
MAXIMUM POWER DISSIPATION

The maximum power that can be safely dissipated by the AD812 is limited by the associated rise in junction temperature. The maximum safe junction temperature for the plastic encapsulated parts is determined by the glass transition temperature of the plastic, about 150°C. Exceeding this limit temporarily may cause a shift in parametric performance due to a change in the stresses exerted on the die by the package. Exceeding a junction temperature of 175°C for an extended period can result in device failure.

While the AD812 is internally short circuit protected, this may not be sufficient to guarantee that the maximum junction temperature (150 degrees) is not exceeded under all conditions. To ensure proper operation, it is important to observe the derating curves.

It must also be noted that in high (noninverting) gain configurations (with low values of gain resistor), a high level of input overdrive can result in a large input error current, which may result in a significant power dissipation in the input stage. This power must be included when computing the junction temperature rise due to total internal power.



Plot of Maximum Power Dissipation vs. Temperature

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the AD812 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

General Considerations

The AD812 is a wide bandwidth, dual video amplifier which offers a high level of performance on less than 5.5 mA per amplifier of quiescent supply current. It is designed to offer outstanding performance at closed-loop inverting or noninverting gains of one or greater.

Built on a low cost, complementary bipolar process, and achieving bandwidth in excess of 100 MHz, differential gain and phase errors of better than 0.1% and 0.1° (into 150 Ω), and output current greater than 40 mA, the AD812 is an exceptionally efficient video amplifier. Using a conventional current feedback architecture, its high performance is achieved through careful attention to design details.

Choice of Feedback & Gain Resistors

Because it is a current feedback amplifier, the closed-loop bandwidth of the AD812 depends on the value of the feedback resistor. The bandwidth also depends on the supply voltage. In addition, attenuation of the open-loop response when driving load resistors less than about 250 Ω will affect the bandwidth. Table I contains data showing typical bandwidths at different supply voltages for some useful closed-loop gains when driving a load of 150 Ω. (Bandwidths will be about 20% greater for load resistances above a few hundred ohms.)

The choice of feedback resistor is not critical unless it is important to maintain the widest, flattest frequency response. The resistors recommended in the table are those (metal film values) that will result in the widest 0.1 dB bandwidth. In those applications where the best control of the bandwidth is desired, 1% metal film resistors are adequate. Wider bandwidths can be attained by reducing the magnitude of the feedback resistor (at the expense of increased peaking), while peaking can be reduced by increasing the magnitude of the feedback resistor.

Table I. –3 dB Bandwidth vs. Closed-Loop Gain and Feedback Resistor (R_L = 150 Ω)

V_S	Gain	R_F, Ω	BW, MHz
±15 V	+1	866	145
	+2	715	100
	+10	357	65
	–1	715	100
	–10	357	60
±5 V	+1	750	90
	+2	681	65
	+10	154	45
	–1	715	70
	–10	154	45
+5 V	+1	750	60
	+2	681	50
	+10	154	35
	–1	715	50
	–10	154	35
+3 V	+1	750	50
	+2	681	40
	+10	154	30
	–1	715	40
	–10	154	25

To estimate the –3 dB bandwidth for closed-loop gains or feedback resistors not listed in the above table, the following two pole model for the AD812 many be used:

$$A_{CL} = \frac{G}{S^2\left[\frac{(R_F + Gr_{IN})\,C_T}{2\,\pi f_2}\right] + S\,(R_F + Gr_{IN})\,C_T + 1}$$

where:
A_{CL} = closed-loop gain
G = $1 + R_F/R_G$
r_{in} = input resistance of the inverting input
C_T = "transcapacitance," which forms the open-loop dominant pole with the tranresistance
R_F = feedback resistor
R_G = gain resistor
f_2 = frequency of second (non-dominant) pole
S = $2\,\pi j f$

Appropriate values for the model parameters at different supply voltages are listed in Table II. Reasonable approximations for these values at supply voltages not found in the table can be obtained by a simple linear interpolation between those tabulated values which "bracket" the desired condition.

Table II. Two-Pole Model Parameters at Various Suppy Voltages

V_S	r_{IN} (Ω)	C_T (pF)	f_2 (MHz)
±15	85	2.5	150
±5	90	3.8	125
+5	105	4.8	105
+3	115	5.5	95

As discussed in many amplifier and electronics textbooks (such as Roberge's *Operational Amplifiers: Theory and Practice*), the –3 dB bandwidth for the 2-pole model can be obtained as:

$$f_3 = f_N\,[1 - 2d^2 + (2 - 4d^2 + 4d^4)^{1/2}]^{1/2}$$

where:

$$f_N = \left[\frac{f_2}{(R_F + Gr_{IN})\,C_T}\right]^{1/2}$$

and:

$$d = (1/2)\,[f_2\,(R_F + Gr_{IN})\,C_T]^{1/2}$$

This model will predict –3 dB bandwidth within about 10 to 15% of the correct value when the load is 150 Ω. However, it is not an accurate enough to predict either the phase behavior or the frequency response peaking of the AD812.

Printed Circuit Board Layout Guidelines

As with all wideband amplifiers, printed circuit board parasitics can affect the overall closed-loop performance. Most important for controlling the 0.1 dB bandwidth are stray capacitances at the output and inverting input nodes. Increasing the space between signal lines and ground plane will minimize the coupling. Also, signal lines connecting the feedback and gain resistors should be kept short enough that their associated inductance does not cause high frequency gain errors.

Power Supply Bypassing

Adequate power supply bypassing can be very important when optimizing the performance of high speed circuits. Inductance in the supply leads can (for example) contribute to resonant circuits that produce peaking in the amplifier's response. In addition, if large current transients must be delivered to a load, then large (greater than 1 μF) bypass capacitors are required to produce the best settling time and lowest distortion. Although 0.1 μF capacitors may be adequate in some applications, more elaborate bypassing is required in other cases.

When multiple bypass capacitors are connected in parallel, it is important to be sure that the capacitors themselves do not form resonant circuits. A small (say 5 Ω) resistor may be required in series with one of the capacitors to minimize this possibility.

As discussed below, power supply bypassing can have a significant impact on crosstalk performance.

Achieving Low Crosstalk

Measured crosstalk from the output of amplifier 2 to the input of amplifier 1 of the AD812 is shown in Figure 37. The crosstalk from the output of amplifier 1 to the input of amplifier 2 is a few dB better than this due to the additional distance between critical signal nodes.

A carefully laid-out PC board should be able to achieve the level of crosstalk shown in the figure. The most significant contributors to difficulty in achieving low crosstalk are inadequate power supply bypassing, overlapped input and/or output signal paths, and capacitive coupling between critical nodes.

The bypass capacitors must be connected to the ground plane at a point close to and between the ground reference points for the two loads. (The bypass of the negative power supply is particularly important in this regard.) There are two amplifiers in the package, and low impedance signal return paths must be provided for each load. (Using a parallel combination of 1 μF, 0.1 μF, and 0.01 μF bypass capacitors will help to achieve optimal crosstalk.)

The input and output signal return paths must also be kept from overlapping. Since ground connections are not of perfectly zero impedance, current in one ground return path can produce a voltage drop in another ground return path if they are allowed to overlap.

Electric field coupling external to (and across) the package can be reduced by arranging for a narrow strip of ground plane to be run between the pins (parallel to the pin rows). Doing this on both sides of the board can reduce the high frequency crosstalk by about 5 dB or 6 dB.

Driving Capacitive Loads

When used with the appropriate output series resistor, any load capacitance can be driven without peaking or oscillation. In most cases, less than 50 Ω is all that is needed to achieve an extremely flat frequency response. As illustrated in Figure 41, the AD812 can be very attractive for driving largely capacitive loads. In this case, the AD812's high output short circuit current allows for a 150 V/μs slew rate when driving a 510 pF capacitor.

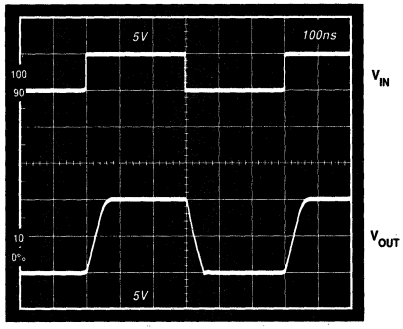

Figure 41. Pulse Response of Circuit of Figure 38 with C_L = 510 pF, R_L = 1 kΩ, R_F = R_G = 715 Ω, R_S = 15 Ω

Overload Recovery

There are three important overload conditions to consider. They are due to input common mode voltage overdrive, input current overdrive, and output voltage overdrive . When the amplifier is configured for low closed-loop gains, and its input common-mode voltage range is exceeded, the recovery time will be very fast, typically under 10 ns. When configured for a higher gain, and overloaded at the output, the recovery time will also be short. For example, in a gain of +10, with 6 dB of input overdrive, the recovery time of the AD812 is about 10 ns.

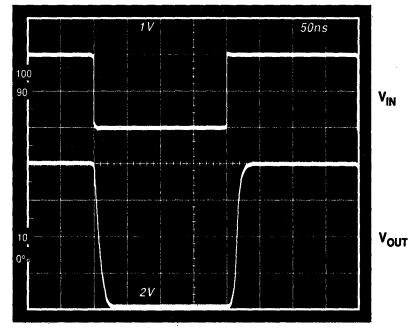

Figure 42. 6 dB Overload Recovery; G = 10, R_L = 500 Ω, V_S = ±5 V

In the case of high gains with very high levels of input overdrive, a longer recovery time may occur. For example, if the input common-mode voltage range is exceeded in a gain of +10, the recovery time will be on the order of 100 ns. This is primarily due to current overloading of the input stage.

As noted in the warning under "Maximum Power Dissipation", a high level of input overdrive in a high noninverting gain circuit can result in a large current flow in the input stage. For differential input voltages of less than about 1.25 V, this will be internally limited to less than 20 mA (decreasing with supply voltage). For input overdrives which result in higher differential input voltages, power dissipation in the input stage must be considered. It is recommended that external diode clamps be used in cases where the differential input voltage is expected to exceed 1.25 V.

High Performance Video Line Driver

At a gain of +2, the AD812 makes an excellent driver for a back terminated 75 Ω video line. Low differential gain and phase errors and wide 0.1 dB bandwidth can be realized over a wide range of power supply voltage. Outstanding gain and group delay matching are also attainable over the full operating supply voltage range.

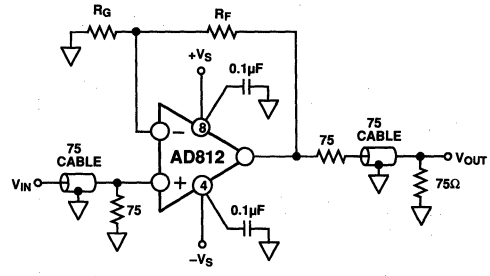

Figure 43. Gain of +2 Video Line Driver (R_F = R_G from Table I)

Operation Using a Single Supply

The AD812 will operate with total supply voltages from 36 V down to 2.4 V. With proper biasing (see Figure 50), it can be an outstanding single supply video amplifier. Since the input and output voltage ranges extend to within 1 volt of the supply rails, it will handle a 1.3 V p-p signal on a single 3.3 V supply, or a 3 V p-p signal on a single 5 V supply. The small signal, 0.1 dB bandwidths will exceed 10 MHz in either case, and the large signal bandwidths will exceed 6 MHz.

The capacitively coupled cable driver in Figure 50 will achieve outstanding differential gain and phase errors of 0.07% and 0.06 degrees respectively on a single 5 V supply. Resistor R2, in this circuit, is selected to optimize the differential gain and phase by operating the amplifier in its most linear region. To optimize the circuit for a 3 V supply, a value of 8 kΩ is recommended for R2.

Single Supply, Low Power Triple Video Amplifier

AD813

FEATURES

Low Cost
Three Video Amplifiers in One Package
Optimized for Driving Cables in Video Systems
Excellent Video Specifications (R_L = 150 Ω)
- **Gain Flatness 0.1 dB to 50 MHz**
- **0.03% Differential Gain Error**
- **0.06° Differential Phase Error**

Low Power
- **Operates on Single +3 V to ±15 V Power Supplies**
- **5.5 mA/Amplifier Max Power Supply Current**

High Speed
- **125 MHz Unity Gain Bandwidth (–3 dB)**
- **500 V/μs Slew Rate**

High Speed Disable Function per Channel
- **Turn-Off Time 80 ns**

Easy to Use
- **50 mA Output Current**
- **Output Swing to 1 V of Rails**

APPLICATIONS

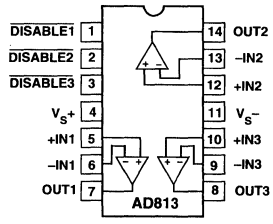
Video Line Driver
LCD Drivers
Computer Video Plug-In Boards
Ultrasound
RGB Amplifier
CCD Based Systems

PRODUCT DESCRIPTION

The AD813 is a low power, single supply triple video amplifier. Each of the three current feedback amplifiers has 50 mA of output current, and is optimized for driving one back terminated video load (150 Ω). The AD813 features gain flatness of 0.1 dB to 50 MHz while offering differential gain and phase error of 0.03% and 0.06°. This makes the AD813 ideal for broadcast and consumer video electronics.

PIN CONFIGURATION

14-Pin DIP & SOIC Package



The AD813 offers low power of 5.5 mA per amplifier max and runs on a single +3 V power supply. The outputs of each amplifier swing to within one volt of either supply rail to easily accommodate video signals. While operating on a single +5 V supply the AD813 still achieves 0.1 dB flatness to 20 MHz and 0.05% & 0.05° of differential gain and phase performance. All this is offered in a small 14-pin plastic DIP or SOIC package. These features make this triple amplifier ideal for portable and battery powered applications where size and power are critical.

The outstanding bandwidth of 125 MHz along with 500 V/μs of slew rate make the AD813 useful in many general purpose, high speed applications where a single +3 V or dual power supplies up to ±15 V are needed. Furthermore the AD813 contains a high speed disable function for each amplifier in order to power down the amplifier or high impedance the output. This can then be used in video multiplexing applications. The AD813 is available in the industrial temperature range of –40°C to +85°C in plastic DIP and SOIC packages as well as chips.

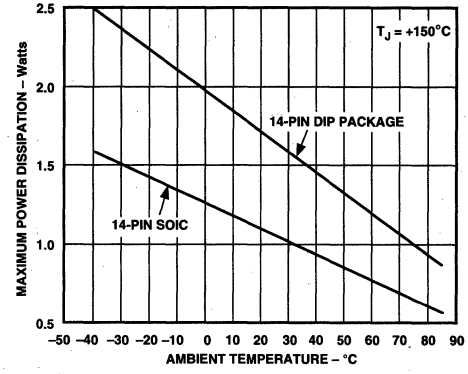
Maximum Power Dissipation

The maximum power that can be safely dissipated by the AD813 is limited by the associated rise in junction temperature. The maximum safe junction temperature for the plastic encapsulated parts is determined by the glass transition temperature of the plastic, about 150°C. Exceeding this limit temporarily may cause a shift in parametric performance due to a change in the stresses exerted on the die by the package. Exceeding a junction temperature of 175°C for an extended period can result in device failure.

While the AD813 is internally short circuit protected, this may not be enough to guarantee that the maximum junction temperature (150°C) is not exceeded under all conditions. To ensure proper operation, it is important to observe the derating curves.

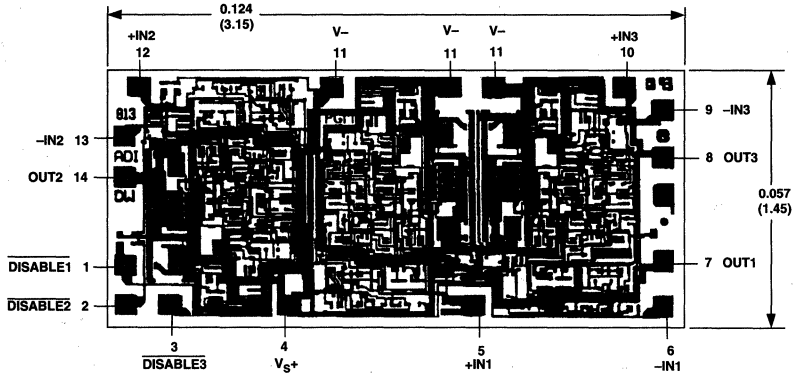
It must also be noted that in (noninverting) gain configurations (with low values of gain resistor), a high level of input overdrive can result in a large input error current, which may result in a significant power dissipation in the input stage. This power must be included when computing the junction temperature rise due to total internal power.



Maximum Power Dissipation vs. Ambient Temperature

METALIZATION PHOTO

Dimensions shown in inches and (mm).



CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the AD813 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

General Consideration

The AD813 is a wide bandwidth, triple video amplifier that offers a high level of performance on less than 5.5 mA per amplifier of quiescent supply current. With its fast acting power down switch, it is designed to offer outstanding functionality and performance at closed-loop inverting or noninverting gains of one or greater.

Built on a low cost, complementary bipolar process, and achieving bandwidth in excess of 100 MHz, differential gain and phase errors of better than 0.1% and 0.1° (into 150 Ω), and output current greater than 40 mA, the AD813 is an exceptionally efficient video amplifier. Using a conventional current feedback architecture, its high performance is achieved through careful attention to design details.

Choice of Feedback & Gain Resistors

Because it is a current feedback amplifier, the closed-loop bandwidth of the AD813 depends on the value of the feedback resistor. The bandwidth also depends on the supply voltage. In addition, attenuation of the open-loop response when driving load resistors less than about 250 Ω will also affect the bandwidth. Table I contains data showing typical bandwidths at different supply voltages for some useful closed-loop gains when driving a load of 150 Ω. (Bandwidths will be about 20% greater for load resistances above a few hundred ohms.)

Table I. –3 dB Bandwidth vs. Closed-Loop Gain and Feedback Resistor, (R_L = 150 Ω)

V_S (V)	Gain	R_F (Ω)	BW (MHz)
±15	+1	866	125
	+2	681	100
	+10	357	60
	–1	681	100
	–10	357	55
±5	+1	750	75
	+2	649	65
	+10	154	40
	–1	649	70
	–10	154	40
+5	+1	715	60
	+2	619	50
	+10	154	30
	–1	619	50
	–10	154	30
+3	+1	681	50
	+2	619	40
	+10	154	25
	–1	619	40
	–10	154	20

The choice of feedback resistor is not critical unless it is important to maintain the widest, flattest frequency response. The resistors recommended in the table are those (metal film values) that will result in the widest 0.1 dB bandwidth. In those applications where the best control of the bandwidth is desired, 1% metal film resistors are adequate. Wider bandwidths can be attained by reducing the magnitude of the feedback resistor (at the expense of increased peaking), while peaking can be reduced by increasing the magnitude of the feedback resistor.

To estimate the –3 dB bandwidth for closed-loop gains or feedback resistors not listed in the above table, the following two pole model for the AD813 may be used:

$$A_{CL} = \frac{G}{S^2\left[\frac{(R_F + Gr_{IN})C_T}{2\,\pi\,f_2}\right] + S\,(R_F + Gr_{IN})\,C_T + 1}$$

Where: A_{CL} = closed-loop gain from "transcapacitance"
G = $1 + R_F/R_G$
r_{IN} = input resistance of the inverting input
C_T = "transcapacitance," which forms the open-loop dominant pole with the transresistance
R_F = feedback resistor
R_G = gain resistor
f_2 = frequency of second (nondominant) pole
s = $2\pi j f$

Appropriate values for the model parameters at different supply voltages are listed in Table II. Reasonable approximations for these values at supply voltages not found in the table can be obtained by a simple linear interpolation between those tabulated values which 'bracket' the desired condition.

Table II. Two Pole Model Parameters at Various Supplies

V_S (V)	r_{IN} (Ω)	C_T (pF)	f_2 (MHz)
±15	85	2.5	150
±5	90	3.8	125
+5	105	4.8	105
+3	115	5.5	95

As discussed in many amplifier and electronics textbooks (such as Roberge's *Operational Amplifiers: Theory and Practice*), the –3 dB bandwidth for the 2-pole model can be obtained as:

$$f_3 = f_n\left[1 - 2d^2 + (2 - 4d^2 + 4d^4)^{1/2}\right]^{1/2}$$

where:

$$f_n = \left[\frac{f_2}{(R_F + Gr_{IN})\,C_T}\right]^{1/2}$$

and:

$$d = \frac{1}{2}\left[f_2(R_F + Gr_{IN})\,C_T\right]^{1/2}$$

This model will predict –3 dB bandwidth within about 10% to 15% of the correct value when the load is 150 Ω. However, it is not accurate enough to predict either the phase behavior or the frequency response peaking of the AD813.

Printed Circuit Board Layout Guidelines

As with all wideband amplifiers, printed circuit board parasitics can affect the overall closed-loop performance. Most important for controlling the 0.1 dB bandwidth are stray capacitances at the output and inverting input nodes. Increasing the space between signal lines and ground plane will minimize the coupling. Also, signal lines connecting the feedback and gain resistors should be kept short enough that their associated inductance does not cause high frequency gain errors.

Power Supply Bypassing

Adequate power supply bypassing can be very important when optimizing the performance of high speed circuits. Inductance in the supply leads can (for example) contribute to resonant circuits that produce peaking in the amplifier's response. In addition, if large current transients must be delivered to a load, then large (greater than 1 µF) bypass capacitors are required to produce the best settling time and lowest distortion. Although 0.1 µF capacitors may be adequate in some applications, more elaborate bypassing is required in other cases.

When multiple bypass capacitors are connected in parallel, it is important to be sure that the capacitors themselves do not form resonant circuits. A small (say 5 Ω) resistor may be required in series with one of the capacitors to minimize this possibility.

As discussed below, power supply bypassing can have a significant impact on crosstalk performance.

Achieving Low Crosstalk

Measured crosstalk from the output of Amplifier 2 to the input of Amplifier 1 of the AD813 is shown in Figure 37. All other crosstalk combinations, (from the output of one amplifier to the input of another), are a few dB better than this due to the additional distance between critical signal nodes.

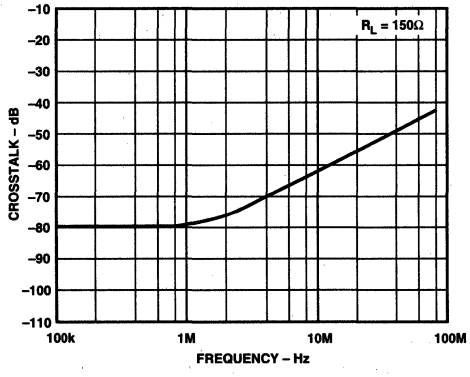

Figure 37. Worst Case Crosstalk vs. Frequency

A carefully laid-out PC board should be able to achieve the level of crosstalk shown in the figure. The most significant contributors to difficulty in achieving low crosstalk are inadequate power supply bypassing, overlapped input and/or output signal paths, and capacitive coupling between critical nodes.

The bypass capacitors must be connected to the ground plane at a point close to and between the ground reference points for the loads. (The bypass of the negative power supply is particularly important in this regard.) This requires careful planning as there are three amplifiers in the package, and low impedance signal return paths must be provided for each load. (Using a parallel combination of 1 µF, 0.1 µF, and 0.01 µF bypass capacitors will help to achieve optimal crosstalk.)

The input and output signal return paths (to the bypass caps) must also be kept from overlapping. Since ground connections are not of perfectly zero impedance, current in one ground return path can produce a voltage drop in another ground return path if they are allowed to overlap.

Electric field coupling external to (and across) the package can be reduced by arranging for a narrow strip of ground plane to be run between the pins (parallel to the pin rows). Doing this on both sides of the board can reduce the high frequency crosstalk by about 5 dB or 6 dB.

Driving Capacitive Loads

When used with the appropriate output series resistor, any load capacitance can be driven without peaking or oscillation. In most cases, less than 50 Ω is all that is needed to achieve an extremely flat frequency response. As illustrated in Figure 41, the AD813 can be very attractive for driving large capacitive loads. In this case, the AD813's high output short circuit current allows for a 150 V/µs slew rate when driving a 510 pF capacitor.

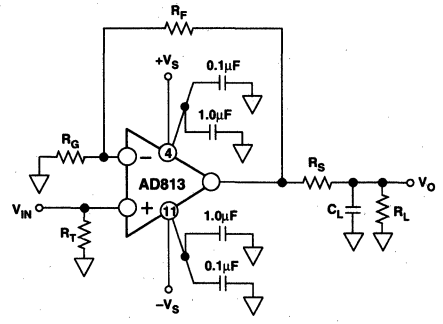

Figure 38. Circuit for Driving a Capacitive Load

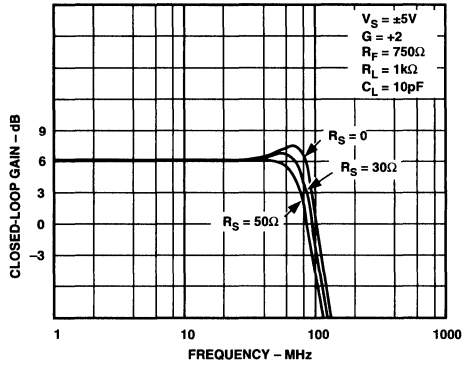

Figure 39. Response to a Small Load Capacitor at V_S = ±5 V

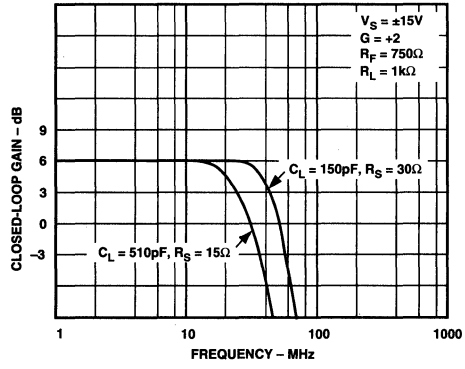

Figure 40. Response to a Large Load Capacitor at V_S = ±15 V

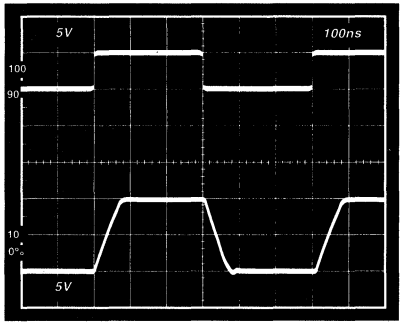

Figure 41. Circuit of Figure 38 Driving a 510 pF Load Capacitor, V_S = ±15 V (R_L = 1 kΩ, R_F = R_G = 750 Ω, R_S = 15 Ω)

Overload Recovery

There are three important overload conditions to consider. They are due to: input common-mode voltage overdrive, output voltage overdrive, and input current overdrive. When the amplifier is configured for low closed-loop gains, and the input common-mode voltage range is exceeded, the recovery time will be very fast, typically under 30 ns. When configured for a higher gain, and overloaded at the output, the recovery time will also be short. For example, in a gain of +10, with 6 dB of input overdrive, the recovery time of the AD813 is about 25 ns (see Figure 42).

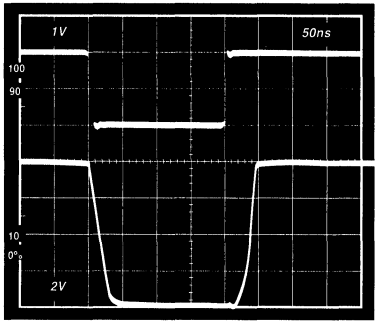

Figure 42. 6 dB Overload Recovery, G = +10, (R_L = 500 Ω, R_F = 357 Ω, V_S = ±5 V)

In the case of high gains with very high levels of input overdrive, a longer recovery time will occur. For example, if the input common-mode voltage range is exceeded in the gain of +10, the recovery time will be on the order of 100 ns. This is primarily due to current overloading of the input stage.

As noted in the warning under "Maximum Power Dissipation," a high level of input overdrive in a high noninverting gain circuit can result in a large current flow in the input stage. Though this current is internally limited to about 40 mA, its effect on the total power dissipation may be significant.

High Performance Video Line Driver

At a gain of +2, the AD813 makes an excellent driver for a back terminated 75 Ω video line. Low differential gain and phase errors and wide 0.1 dB bandwidth can be realized over a wide range of power supply voltage. Excellent gain and group delay matching are also attainable over the full operating supply voltage range.

Figures 47 and 48 show the worst case matching; the match between amplifiers 2 and 3 is typically much better than this.

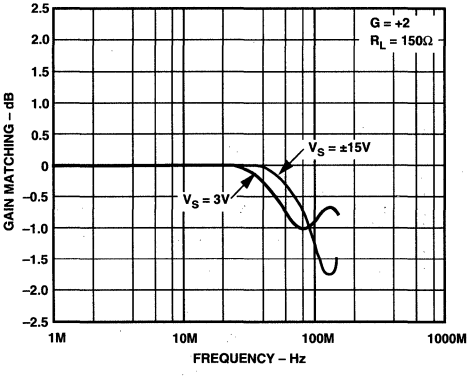

Figure 47. Closed-Loop Gain Matching vs. Frequency

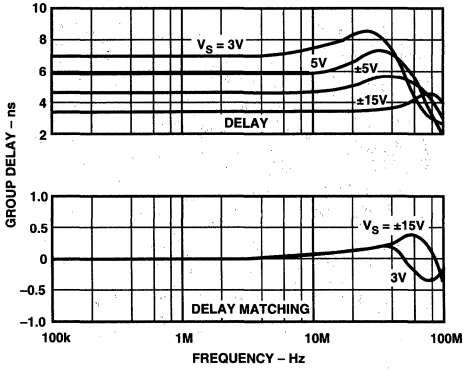

Figure 48. Group Delay and Group Delay Matching vs. Frequency, G = +2, R_L = 150 Ω

Operation Using a Single Supply

The AD813 will operate with total supply voltages from 36 V down to 2.4 V. With proper biasing (see Figure 49) it can make an outstanding single supply video amplifier. Since the input and output voltage ranges extend to within 1 V of the supply rails, it will handle a 1.3 V peak-to-peak signal on a single 3.3 V supply, or a 3 V peak-to-peak signal on a single 5 V supply. The small signal 0.1 dB bandwidths will exceed 10 MHz in either case, and the large signal bandwidths will exceed 6 MHz.

The capacitively coupled cable driver in Figure 49 will achieve outstanding differential gain and phase errors of 0.05% and 0.05 degrees respectively on a single 5 V supply. Resistor R2, in this circuit, is selected to optimize the differential gain and phase by biasing the amplifier in its most linear region.

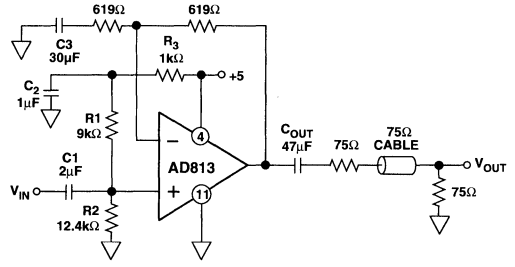

Figure 49. Biasing for Single Supply Operation

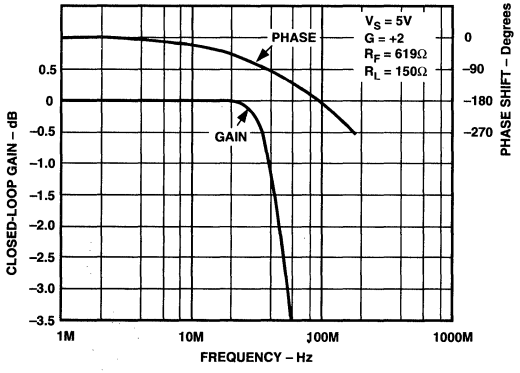

Figure 50. Closed-Loop Gain and Phase vs. Frequency, Circuit of Figure 49

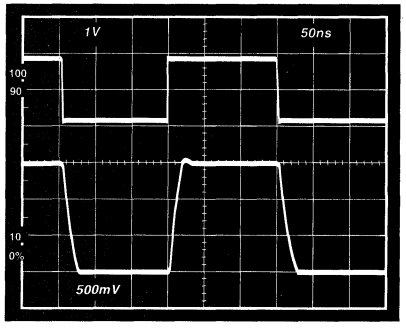

Figure 51. Pulse Response for the Circuit of Figure 49 with $+V_S$ = 5 V

Disable Mode Operation

Pulling the voltage on any one of the Disable pins about 2.5 V down from the positive supply will put the corresponding amplifier into a disabled, powered down, state. In this condition, the amplifier's quiescent supply current drops to about 0.5 mA, its output becomes a high impedance, and there is a high level of isolation from input to output. In the case of the gain of two line driver for example, the impedance at the output node will be about the same as for a 1.4 kΩ resistor (the feedback plus gain resistors) in parallel with a 12.5 pF capacitor and the input to output isolation will be about 65 dB at 1 MHz.

Leaving the Disable pin disconnected (floating) will leave the corresponding amplifier operational, in the enabled state. The input impedance of the disable pins is about 35 kΩ in parallel with a few pF. When grounded, about 50 µA flows out of a disable pin on ±5 V supplies.

Input voltages greater than about 1.5 V peak-to-peak will defeat the isolation. In addition, large signals (greater than 3 V peak-to-peak) applied to the output node will cause the output impedance to drop significantly.

When the Disable pins are driven by complementary output CMOS logic (such as the 74HC04), the disable time is about 80 ns (until the output goes high impedance) and the enable time is about 100 ns (to low impedance output) on ±15 V supplies. When operated on ±15 V supplies, the disable pins should be driven by open drain logic. In this case, pull-up resistors from the disable pins to the plus supply will ensure minimum switching time.

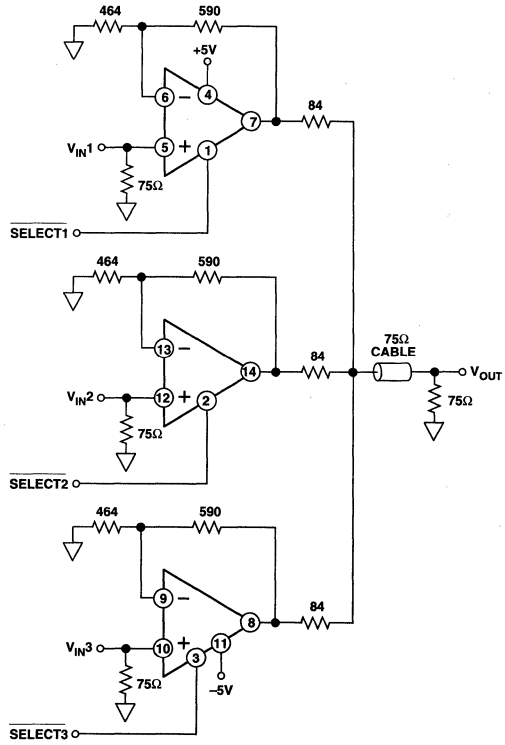

Figure 52. A Fast Switching 3:1 Video Mux (Supply Bypassing Not Shown)

3:1 Video Multiplexer

Wiring the amplifier outputs together will form a 3:1 mux with outstanding gain flatness. Figure 52 shows a recommended configuration which results in –0.1 dB bandwidth of 20 MHz and OFF channel isolation of 60 dB at 10 MHz on ±5 V supplies. The time to switch between channels is about 180 ns. Switching time is only slightly affected by signal level.

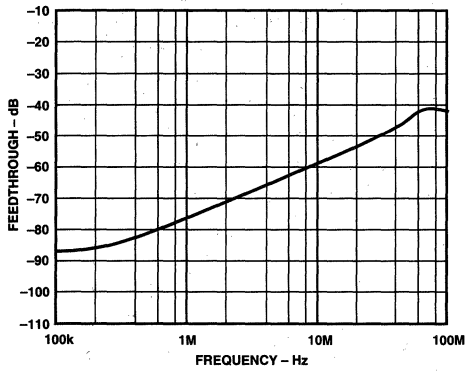

Figure 54. 3:1 Mux OFF Channel Feedthrough vs. Frequency

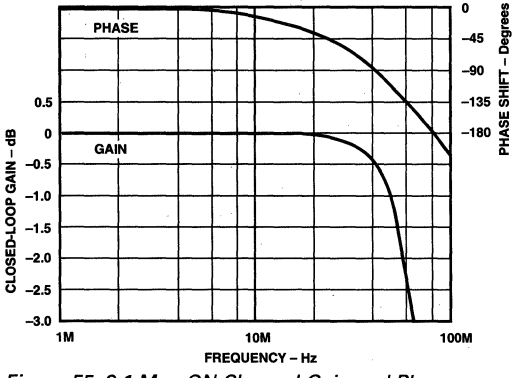

Figure 55. 3:1 Mux ON Channel Gain and Phase vs. Frequency

Single Supply Differential Line Driver

Due to its outstanding overall performance on low supply voltages, the AD813 makes possible exceptional differential transmission on very low power. The circuit of Figure 56 will convert a single-ended, ground referenced signal to a differential signal whose common-mode reference is set to one half the supply voltage. This allows for a greater than 2 V peak-to-peak signal swing on a single 3 V power supply. A bandwidth over 30 MHz is achieved with 20 mA of output drive on only 30 mW of quiescent power (excluding load current).

High Speed, Low Power Wide Supply Range Amplifier

AD817

FEATURES
Low Cost
High Speed
50 MHz Unity Gain Bandwidth
350 V/μs Slew Rate
45 ns Settling Time to 0.1% (10 V Step)
Flexible Power Supply
Specified for Single (+5 V) and Dual (±5 V to ±15 V) Power Supplies
Low Power: 7.5 mA max Supply Current
High Output Drive Capability
Drives Unlimited Capacitive Load
50 mA Minimum Output Current
Excellent Video Performance
70 MHz 0.1 dB Bandwidth (Gain = +1)
0.04% & 0.08° Differential Gain & Phase Errors @ 3.58 MHz
Available in 8-Pin SOIC and 8-Pin Plastic Mini-DIP

CONNECTION DIAGRAM
8-Pin Plastic Mini-DIP (N), and SOIC (R) Packages

PRODUCT DESCRIPTION

The AD817 is a low cost, low power, single/dual supply, high speed op amp which is ideally suited for a broad spectrum of signal conditioning and data acquisition applications. This breakthrough product also features high output current drive capability and the ability to drive an unlimited capacitive load while still maintaining excellent signal integrity.

The 50 MHz unity gain bandwidth, 350 V/μs slew rate and settling time of 45 ns (0.1%) make possible the processing of high speed signals common to video and imaging systems. Furthermore, professional video performance is attained by offering differential gain & phase errors of 0.04% & 0.08° @ 3.58 MHz and 0.1 dB flatness to 70 MHz (gain = +1).

The AD817 is fully specified for operation with a single +5 V power supply and with dual supplies from ±5 V to ±15 V. This power supply flexibility, coupled with a very low supply current of 7.5 mA and excellent ac characteristics under all power supply conditions, make the AD817 the ideal choice for many demanding yet power sensitive applications.

In applications such as ADC buffers and line drivers the AD817 simplifies the design task with its unique combination of a 50 mA minimum output current and the ability to drive unlimited capacitive loads.

The AD817 is available in 8-pin plastic mini-DIP and SOIC packages.

Maximum Power Dissipation vs. Temperature for Different Package Types

ESD SUSCEPTIBILITY

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 volts, which readily accumulate on the human body and on test equipment, can discharge without detection. Although the AD817 features proprietary ESD protection circuitry, permanent damage may still occur on these devices if they are subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid any performance degradation or loss of functionality.

DRIVING CAPACITIVE LOADS

The internal compensation of the AD817, together with its high output current drive, permit excellent large signal performance while driving extremely high capacitive loads.

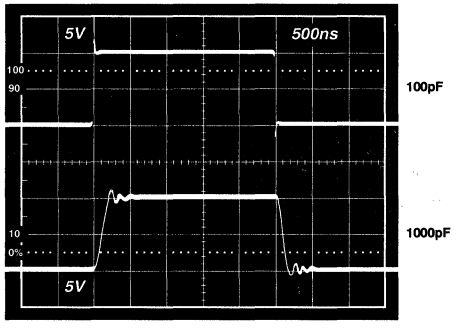

Figure 30b. Inverting Amplifier Pulse Response While Driving Capacitive Loads

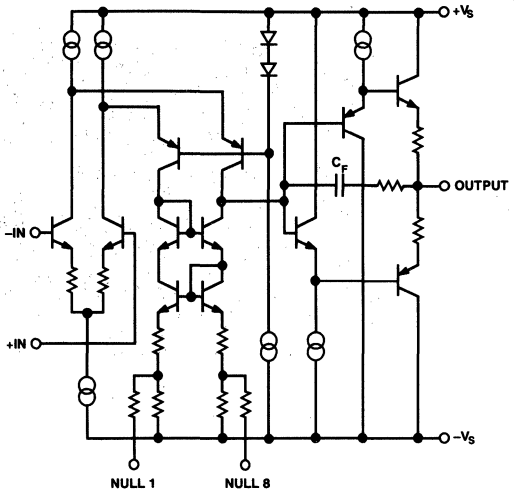

Figure 31. Simplified Schematic

THEORY OF OPERATION

The AD817 is a low cost, wide band, high performance operational amplifier which effectively drives heavy capacitive or resistive loads. It also provides a constant slew rate, bandwidth and settling time over its entire specified temperature range.

The AD817 (Figure 31) consists of a degenerated NPN differential pair driving matched PNPs in a folded-cascode gain stage. The output buffer stage employs emitter followers in a class AB amplifier which delivers the necessary current to the load while maintaining low levels of distortion.

The capacitor, C_F, in the output stage mitigates the effect of capacitive loads. At low frequencies, and with low capacitive loads, the gain from the compensation node to the output is very close to unity. In this case, C_F is bootstrapped and does not contribute to the overall compensation capacitance of the device. As the capacitive load is increased, a pole is formed with the output impedance of the output stage. This reduces the gain, and therefore, C_F is incompletely bootstrapped. Effectively, some fraction of C_F contributes to the overall compensation capacitance, reducing the unity gain bandwidth. As the load capacitance is further increased, the bandwidth continues to fall, maintaining the stability of the amplifier.

INPUT CONSIDERATIONS

An input protection resistor (R_{IN} in Figure 22) is required in circuits where the input to the AD817 will be subjected to transient or continuous overload voltages exceeding the +6 V maximum differential limit. This resistor provides protection for the input transistors by limiting their maximum base current.

For high performance circuits, it is recommended that a "balancing" resistor be used to reduce the offset errors caused by bias current flowing through the input and feedback resistors. The balancing resistor equals the parallel combination of R_{IN} and R_F and thus provides a matched impedance at each input terminal. The offset voltage error will then be reduced by more than an order of magnitude.

GROUNDING & BYPASSING

When designing high frequency circuits, some special precautions are in order. Circuits must be built with short interconnect leads. When wiring components, care should be taken to provide a low resistance, low inductance path to ground. Sockets should be avoided, since their increased interlead capacitance can degrade circuit bandwidth.

Feedback resistors should be of low enough value (<1 kΩ) to assure that the time constant formed with the inherent stray capacitance at the amplifier's summing junction will not limit performance. This parasitic capacitance, along with the parallel resistance of R_F/R_{IN}, form a pole in the loop transmission which may result in peaking. A small capacitance (1–5 pF) may be used in parallel with the feedback resistor to neutralize this effect.

Power supply leads should be bypassed to ground as close as possible to the amplifier pins. Ceramic disc capacitors of 0.1 μF are recommended.

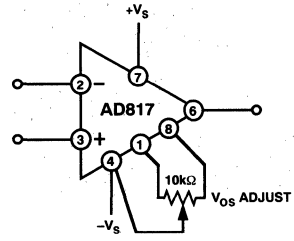

Figure 32. Offset Null Configuration

OFFSET NULLING

The input offset voltage of the AD817 is inherently very low. However, if additional nulling is required, the circuit shown in Figure 32 can be used. The null range of the AD817 in this configuration is ±15 mV.

AD817 SETTLING TIME

Settling time is comprised primarily of two regions. The first is the slew time in which the amplifier is overdriven, where the output voltage rate of change is at its maximum. The second is the linear time period required for the amplifier to settle to within a specified percent of the final value.

Measuring the rapid settling time of AD817 (45 ns to 0.1% and 70 ns to 0.01%—10 V step) requires applying an input pulse with a very fast edge and an extremely flat top. With the AD817 configured in a gain of −1, a clamped false summing junction responds when the output error is within the sum of two diode voltages (≈ 1 volt). The signal is then amplified 20 times by a clamped amplifier whose output is connected directly to a sampling oscilloscope. Figures 33 and 34 show the settling time of the AD817, with a 10 volt step applied.

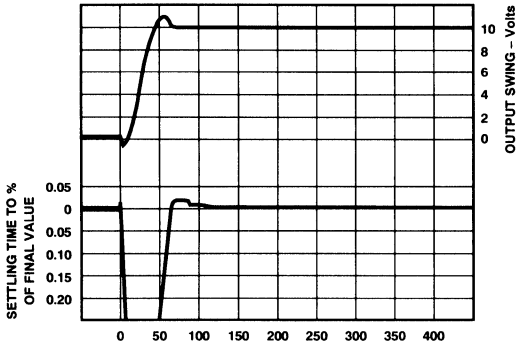

Figure 33. Settling Time in ns 0 V to +10 V

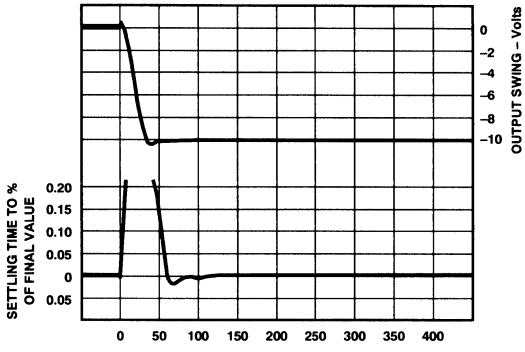

Figure 34. Settling Time in ns 0 V to −10 V

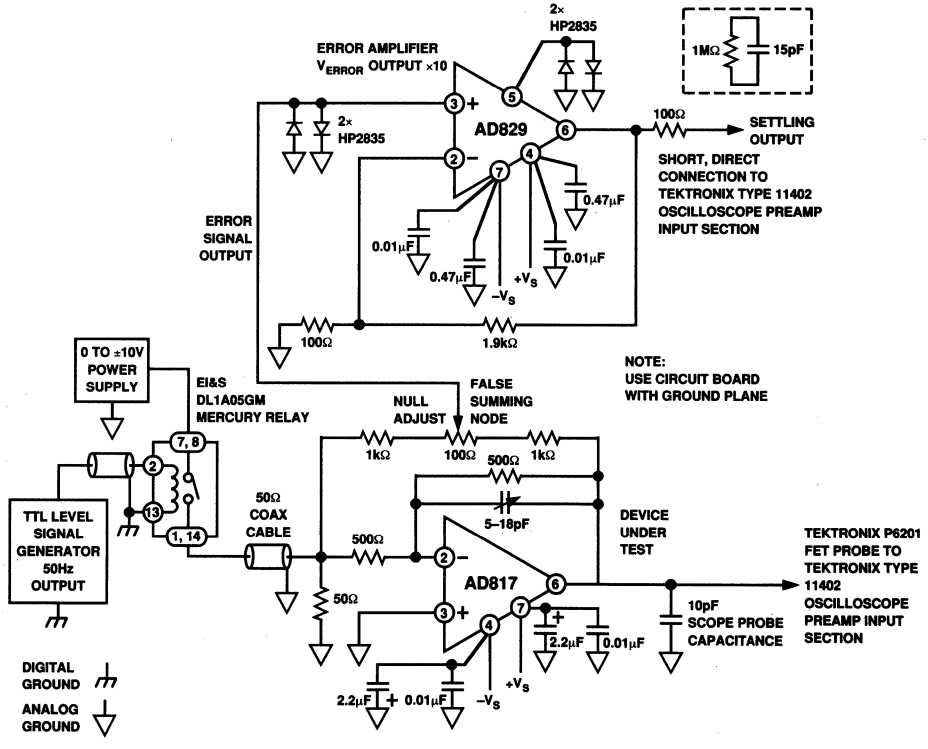

Figure 35. Settling Time Test Circuit

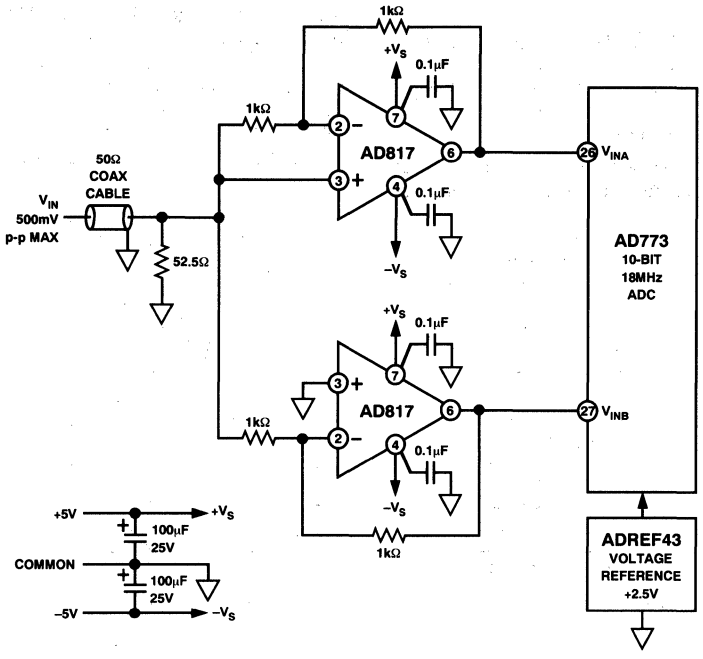

Figure 36. A Differential Input Buffer for High Bandwidth ADCs

A HIGH PERFORMANCE ADC INPUT BUFFER

High performance analog to digital converters (ADCs) require input buffers with correspondingly high bandwidths and very low levels of distortion. Typical requirements include distortion levels of −60 dB to −70 dB for a 1 volt p-p signal and bandwidths of 10 MHz or more. In addition, an ADC buffer may need to drive very large capacitive loads.

The circuit of Figure 36 is useful for driving high speed converters such as the differential input of the AD733, 10-bit ADC. This circuit may be used with other converters with only minor modifications. Using the AD817 provides the user with the option of either operating the buffer in differential mode or from a single +5 volt supply. Operating from a +5 volt power supply helps to avoid overdriving the ADC — a common problem with buffers operating at higher supply voltages.

SINGLE SUPPLY OPERATION

Another exciting feature of the AD817 is its ability to perform well in a single supply configuration. The AD817 is ideally suited for applications that require low power dissipation and high output current and those which need to drive large capacitive loads, such as high speed buffering and instrumentation.

Referring to Figure 37, careful consideration should be given to the proper selection of component values. The choices for this particular circuit are: R1+ R3//R2 combine with C1 to form a low frequency corner of approximately 300 Hz.

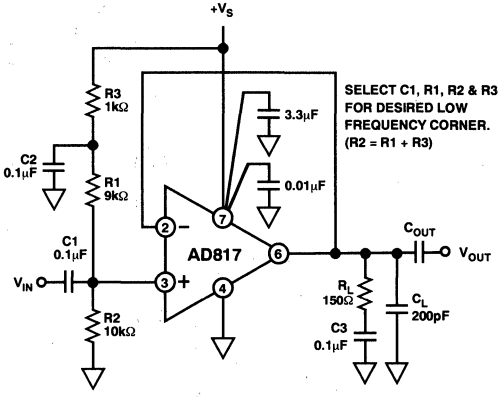

Figure 37. Single Supply Amplifier Configuration

Combining R3 with C2 forms a low-pass filter with a corner frequency of 1.5 kHz. This is needed to maintain amplifier PSRR, since the supply is connected to V_{IN} through the input divider. The values for R_L and C_L were chosen to demonstrate the AD817's exceptional output drive capability. In this configuration, the output is centered around 2.5 V. In order to eliminate the static dc current associated with this level, C3 was inserted in series with R_L.

HIGH SPEED DAC BUFFER

The wide bandwidth and fast settling time of the AD817 make it a very good output buffer for high speed current-output D/A converters like the AD668. As shown in Figure 38, the op amp establishes a summing node at ground for the DAC output. The output voltage is determined by the amplifier's feedback resistor (10.24 V for a 1 kΩ resistor). Note that since the DAC generates a positive current to ground, the voltage at the amplifier output will be negative. A 100 Ω series resistor between the noninverting amplifier input and ground minimizes the offset effects of op amp input bias currents.

PRODUCT DESCRIPTION

The AD818 is a low cost, video op amp optimized for use in video applications which require gains equal to or greater than +2 or −1. The AD818 low differential gain and phase errors, single supply functionality, low power and high output drive make it ideal for cable driving applications such as video cameras and professional video equipment.

With video specs like 0.1 dB flatness to 55 MHz and low differential gain and phase errors of 0.01% and 0.05°, along with 50 mA of output current, the AD818 is an excellent choice for any video application. The 130 MHz 3 dB bandwidth (G = +2) and 500 V/μs slew rate make the AD818 useful in many high speed applications including: video monitors, CATV, color copiers, image scanners and fax machines.

The AD818 is fully specified for operation with a single +5 V power supply and with dual supplies from ±5 V to ±15 V. This power supply flexibility, coupled with a very low supply current of 7.5 mA and excellent ac characteristics under all power supply conditions, make the AD818 the ideal choice for many demanding yet power sensitive applications.

The AD818 is a voltage feedback op amp and excels as a gain stage in high speed and video systems (gain = >2 or −1). It achieves a settling time of 45 ns to 0.1%, with a low input offset voltage of 2 mV max.

The AD818 is available in low cost, small 8-pin plastic mini-DIP and SOIC packages.

Lead Temperature Range (Soldering 10 seconds) . . . . +300°C

NOTES
[1]Stresses above those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. This is a stress rating only and functional operation of the device at these or any other conditions above those indicated in the operational section of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.
[2]Specification is for device in free air: 8-pin plastic package, θ_{JA} = 90°C/watt; 8-pin SOIC package, θ_{JA} = 155°C/watt.

Maximum Power Dissipation vs. Temperature for Different Package Types

ESD SUSCEPTIBILITY

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 volts, which readily accumulate on the human body and on test equipment, can discharge without detection. Although the AD817 features proprietary ESD protection circuitry, permanent damage may still occur on these devices if they are subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid any performance degradation or loss of functionality.

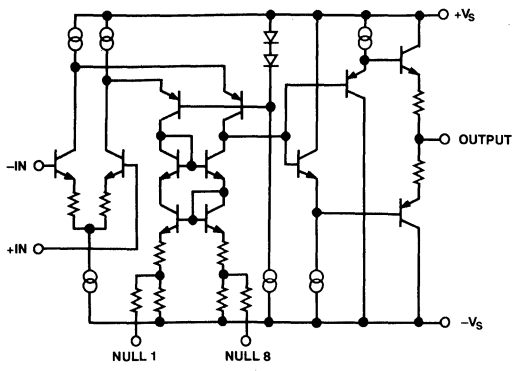

Figure 34. AD818 Simplified Schematic

THEORY OF OPERATION

The AD818 is a low cost, video operational amplifier designed to excel in high performance, high output current video applications.

The AD818 (Figure 34) consists of a degenerated NPN differential pair driving matched PNPs in a folded-cascode gain stage. The output buffer stage employs emitter followers in a class AB amplifier which delivers the necessary current to the load, while maintaining low levels of distortion.

The AD818 will drive terminated cables and capacitive loads of 10 pF or less. As the closed-loop gain is increased, the AD818 will drive heavier cap loads without oscillating.

INPUT CONSIDERATIONS

An input protection resistor (R_{IN} in Figure 28) is required in circuits where the input to the AD818 will be subjected to transient of continuous overload voltages exceeding the ±6 V maximum differential limit. This resistor provides protection for the input transistors by limiting their maximum base current.

For high performance circuits, it is recommended that a "balancing" resistor be used to reduce the offset errors caused by bias current flowing through the input and feedback resistors. The balancing resistor equals the parallel combination of R_{IN} and R_F and thus provides a matched impedance at each input terminal. The offset voltage error will then be reduced by more than an order of magnitude.

GROUNDING AND BYPASSING

When designing high frequency circuits, some special precautions are in order. Circuits must be built with short interconnect leads. When wiring components, care should be taken to provide a low resistance, low inductance path to ground. Sockets should be avoided, since their increased interlead capacitance can degrade circuit bandwidth.

Feedback resistors should be of low enough value (≤1 kΩ) to assure that the time constant formed with the inherent stray capacitance at the amplifier's summing junction will not limit performance. This parasitic capacitance, along with the parallel resistance of R_F/R_{IN}, form a pole in the loop transmission which may result in peaking. A small capacitance (1–5 pF) may be used in parallel with the feedback resistor to neutralize this effect.

Power supply leads should be bypassed to ground as close as possible to the amplifier pins. Ceramic disc capacitors of 0.1 μF are recommended.

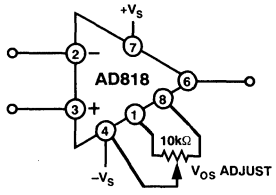

Figure 35. Offset Null Configuration

OFFSET NULLING

The input offset voltage of the AD818 is inherently very low. However, if additional nulling is required, the circuit shown in Figure 35 can be used. The null range of the AD818 in this configuration is ±10 mV.

SINGLE SUPPLY OPERATION

Another exciting feature of the AD818 is its ability to perform well in a single supply configuration. The AD818 is ideally suited for applications that require low power dissipation and high output current.

Referring to Figure 36, careful consideration should be given to the proper selection of component values. The choices for this particular circuit are: R1 + R3||R2 combine with C1 to form a low frequency corner of approximately 10 kHz. C4 was inserted in series with R4 to maintain amplifier stability at high frequency.

Combining R3 with C2 forms a low pass filter with a corner frequency of approximately 500 Hz. This is needed to maintain amplifier PSRR, since the supply is connected to V_{IN} through the input divider. The values for R2 and C2 were chosen to demonstrate the AD818's exceptional output drive capability. In this configuration, the output is centered around 2.5 V. In order to eliminate the static dc current associated with this level, C3 was inserted in series with R_L.

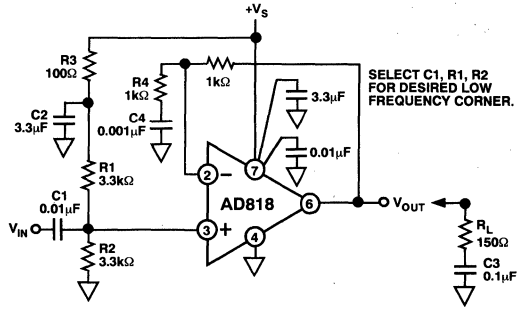

Figure 36. Single Supply Amplifier Configuration

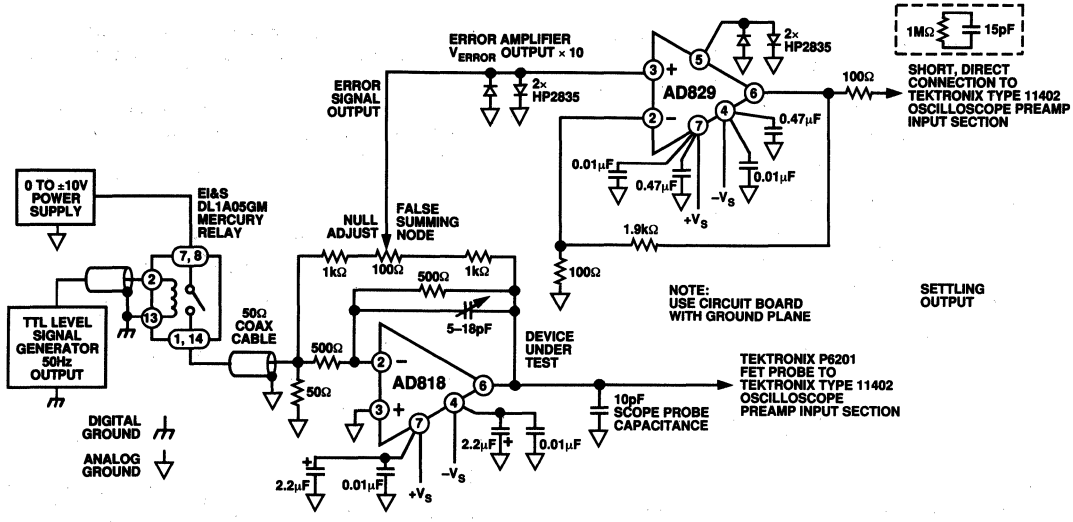

Figure 37. Settling Time Test Circuit

AD818 SETTLING TIME

Settling time is comprised primarily of two regions. The first is the slew time in which the amplifier is overdriven, where the output voltage rate of change is at its maximum. The second is the linear time period required for the amplifier to settle to within a specified percent of the final value.

Measuring the rapid settling time of AD818 (45 ns to 0.1% and 80 ns to 0.01%—10 V step) requires applying an input pulse with a very fast edge and an extremely flat top. With the AD818 configured in a gain of −1, a clamped false summing junction responds when the output error is within the sum of two diode voltages (approximately 1 volt). The signal is then amplified 20 times by a clamped amplifier whose output is connected directly to a sampling oscilloscope.

A High Performance Video Line Driver

The buffer circuit shown in Figure 38 will drive a back-terminated 75 Ω video line to standard video levels (1 V p-p) with 0.1 dB gain flatness to 55 MHz with only 0.05° and 0.01% differential phase and gain at the 3.58 MHz NTSC subcarrier frequency. This level of performance, which meets the requirements for high-definition video displays and test equipment, is achieved using only 7 mA quiescent current.

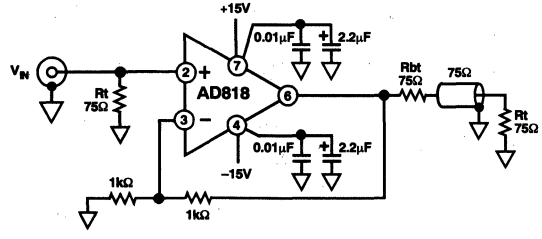

Figure 38. Video Line Driver

DIFFERENTIAL LINE RECEIVER

The differential receiver circuit of Figure 39 is useful for many applications from audio to video. It allows extraction of a low level signal in the presence of common-mode noise. As shown in Figure 40, the AD818 provides this function with only 10nV/$\sqrt{\text{Hz}}$ noise at the output.

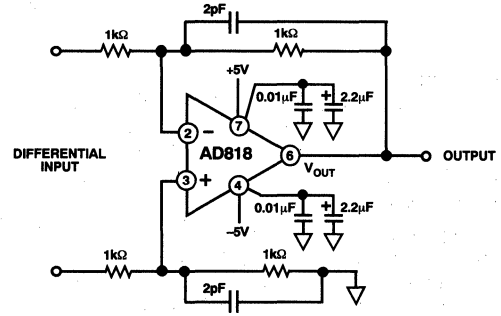

Figure 39. Differential Line Receiver

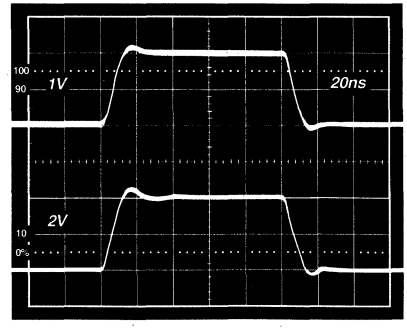

Figure 40. Performance of Line Receiver, R_L = 150 Ω, G = +2

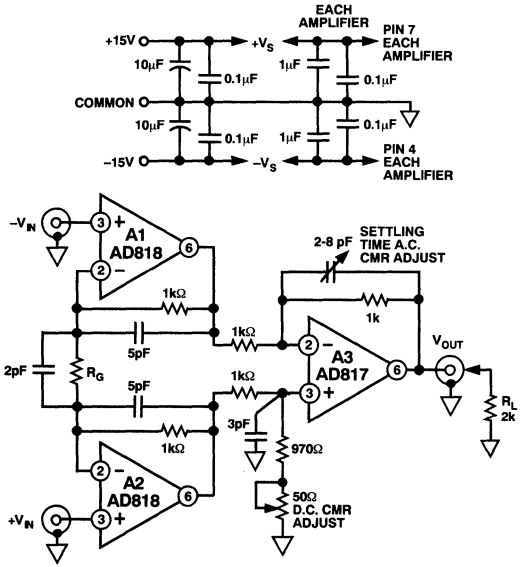
A HIGH SPEED, THREE OP AMP IN AMP

The circuit of Figure 41 uses three high speed op amps: two AD818s and an AD817. This high speed circuit lends itself well to CCD imaging and other video speed applications. It has the optional flexibility of both dc and ac trims for common-mode rejection, plus the ability to adjust for minimum settling time.



BANDWIDTH, SETTLING TIME, & TOTAL HARMONIC DISTORTION VS. GAIN

GAIN	R_G	CADJ (pF)	SMALL SIGNAL BANDWIDTH	SETTLING TIME TO 0.1%	THD + NOISE BELOW INPUT LEVEL @ 10kHz

Single Supply, Rail-to-Rail Low Power FET-Input Op Amps

AD820/AD822

FEATURES

TRUE SINGLE SUPPLY OPERATION
- Output Swings Rail to Rail
- Input Voltage Range Extends Below Ground
- Single Supply Capability from +3 V to +36 V
- Dual Supply Capability from ±1.5 V to ±18 V

HIGH LOAD DRIVE
- Capacitive Load Drive of 350 pF, G = 1
- Minimum Output Current of 15 mA

EXCELLENT AC PERFORMANCE FOR LOW POWER
- 800 μA Max Quiescent Current per Amplifier
- Unity Gain Bandwidth: 1.8 MHz
- Slew Rate of 3.0 V/μs

GOOD DC PERFORMANCE
- 800 μV Max Input Offset Voltage
- 2 μV/°C Typ Offset Voltage Drift
- 25 pA Max Input Bias Current

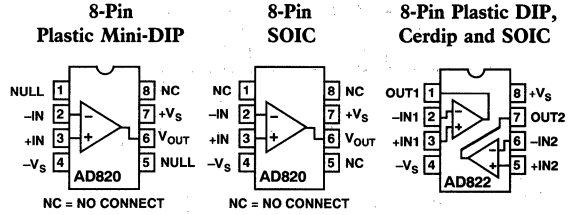
LOW NOISE
- 13 nV/$\sqrt{Hz}$ @ 10 kHz

NO PHASE INVERSION

APPLICATIONS

Battery Powered Precision Instrumentation
Photodiode Preamps
Active Filters
12- to 14-Bit Data Acquisition Systems
Medical Instrumentation
Low Power References and Regulators

CONNECTION DIAGRAMS



PRODUCT DESCRIPTION

The AD820/AD822 are precision, low power FET input op amps that can operate from a single supply of +3.0 V to +36 V, or dual supplies of ±1.5 V to ±18 V. They have true single supply capability with an input voltage range extending below the negative rail, allowing them to accommodate input signals below ground in the single supply mode. Output voltage swing extends to within 10 mV of each rail providing the maximum output dynamic range.

Offset voltage of 800 μV max, offset voltage drift of 2 μV/°C, input bias currents below 25 pA and low input voltage noise provide dc precision with source impedances up to a Gigaohm. 1.8 MHz unity gain bandwidth, −93 dB THD at 10 kHz and 3 V/μs slew rate are provided with a low supply current of 800 μA per amplifier. The AD820 and AD822 drive up to 350 pF of direct capacitive load as a follower, and provides a minimum output current of 15 mA. This allows the amplifier to handle a wide range of load conditions. This combination of ac and dc performance, plus the outstanding load drive capability, results in an exceptionally versatile amplifier for the single supply user.

The AD820 and AD822 are available in four performance grades. The A and B grades are rated over the industrial temperature range of −40°C to +85°C. There is a 3 volt grade—the AD820A-3V or AD822A-3V, rated over the industrial temperature range. The AD822 is also available in a mil grade, is rated over the military temperature range of −55°C to +125°C, and is processed on a standard military drawing.

The AD820 is offered in 8-pin plastic DIP and SOIC packaging while the AD822 is offered in three varieties of 8-pin package: plastic DIP, hermetic cerdip and surface mount (SOIC) as well as die form.

NOTES
[1]See standard military drawing for 883B specifications.
[2]This is a functional specification. Amplifier bandwidth decreases when the input common-mode voltage is driven in the range ($+V_S$ –1 V) to $+V_S$. Common-mode error voltage is typically less than 5 mV with the common-mode voltage set at 1 volt below the positive supply.
[3]V_{OL}–V_{EE} is defined as the difference between the lowest possible output voltage (V_{OL}) and the minus voltage supply rail (V_{EE}).
V_{CC}–V_{OH} is defined as the difference between the highest possible output voltage (V_{OH}) and the positive supply voltage (V_{CC}).
Specifications subject to change without notice.

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the AD820 and AD822 feature proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

ABSOLUTE MAXIMUM RATINGS[1]

Supply Voltage . . . . . ±18 V
Internal Power Dissipation
  Plastic DIP (N) . . . . . Observe Derating Curves
  Cerdip (Q) . . . . . Observe Derating Curves
  SOIC (R) . . . . . Observe Derating Curves
Input Voltage . . . . . ($+V_S$ + 0.2 V) to − (20 V + V_S)
Output Short Circuit Duration . . . . . Indefinite
Differential Input Voltage . . . . . ±30 V
Storage Temperature Range (N) . . . . . −65°C to +125°C
Storage Temperature Range (Q) . . . . . −65°C to +150°C
Storage Temperature Range (R) . . . . . −65°C to +150°C
Operating Temperature Range
  AD820A/B . . . . . −40°C to +85°C
  AD822A/B . . . . . −40°C to +85°C
  AD822S . . . . . −55°C to +125°C
Lead Temperature Range
  (Soldering 60 sec) . . . . . +260°C

NOTES
[1]Stresses above those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. This is a stress rating only and functional operation of the device at these or any other conditions above those indicated in the operational section of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.
[2]8-Pin Plastic DIP Package: θ_{JA} = 90°C/Watt
8-Pin Cerdip Package: θ_{JA} = 110°C/Watt
8-Pin SOIC Package: θ_{JA} = 160°C/Watt

MAXIMUM POWER DISSIPATION

The maximum power that can be safely dissipated by the AD820 or AD822 is limited by the associated rise in junction temperature. For plastic packages, the maximum safe junction temperature is 145°C. For the cerdip packages, the maximum junction temperature is 175°C. If these maximums are exceeded momentarily, proper circuit operation will be restored as soon as the die temperature is reduced. Leaving the device in the "overheated" condition for an extended period can result in device burnout. To ensure proper operation, it is important to observe the derating curves shown in Figure 24.

While the AD820 and AD822 are internally short circuit protected, this may not be sufficient to guarantee that the maximum junction temperature is not exceeded under all conditions. With power supplies ±12 volts (or less) at an ambient temperature of +25°C or less, if the output node is shorted to a supply rail, then the amplifier will not be destroyed, even if this condition persists for an extended period.

ORDERING GUIDE

Model[1]	Temperature Range	Package Description	Package Option[2]
AD820AN	−40°C to +85°C	8-Pin Plastic Mini-DIP	N-8

APPLICATION NOTES

INPUT CHARACTERISTICS

In the AD820 and AD822, n-channel JFETs are used to provide a low offset, low noise, high impedance input stage. Minimum input common-mode voltage extends from 0.2 V below $-V_S$ to 1 V less than $+V_S$. Driving the input voltage closer to the positive rail will cause a loss of amplifier bandwidth (as can be seen by comparing the large signal responses shown in Figures 31 and 34) and increased common-mode voltage error as illustrated in Figure 17.

The AD820 and AD822 do not exhibit phase reversal for input voltages up to and including $+V_S$. Figure 39a shows the response of a voltage follower to a 0 V to +5 V ($+V_S$) square wave input. The input and output are superimposed. The output tracks the input up to $+V_S$ without phase reversal. The reduced bandwidth above a 4 V input causes the rounding of the output wave form. For input voltages greater than $+V_S$, a resistor in series with the noninverting input will prevent phase reversal, at the expense of greater input voltage noise. This is illustrated in Figure 39b.

Since the input stage uses n-channel JFETs, input current during normal operation is negative; the current flows out from the input terminals. If the input voltage is driven more positive than $+V_S - 0.4V$, the input current will reverse direction as internal device junctions become forward biased. This is illustrated in Figure 4.

A current limiting resistor should be used in series with the input of the AD820 or AD822 if there is a possibility of the input voltage exceeding the positive supply by more than 300 mV, or if an input voltage will be applied to the AD820 or AD822 when $\pm V_S = 0$. The amplifier will be damaged if left in that condition for more than 10 seconds. A 1 kΩ resistor allows the amplifier to withstand up to 10 volts of continuous overvoltage, and increases the input voltage noise by a negligible amount.

Input voltages less than $-V_S$ are a completely different story. The amplifier can safely withstand input voltages 20 volts below the minus supply voltage as long as the total voltage from the positive supply to the input terminal is less than 36 volts. In addition, the input stage typically maintains picoamp level input currents across that input voltage range.

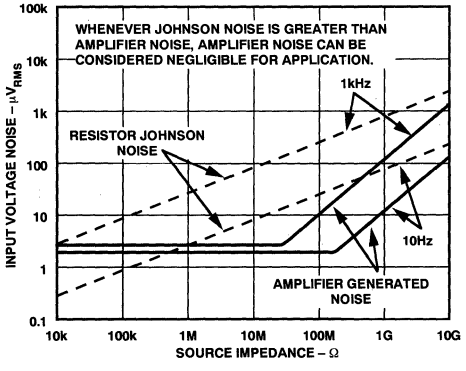

Figure 40. Total Noise vs. Source Impedance

The AD820 and AD822 are designed for 13 nV/$\sqrt{\text{Hz}}$ wideband input voltage noise and maintain low noise performance to low frequencies (refer to Figure 11). This noise performance, along with the low input current and current noise means that the AD820 and AD822 contribute negligible noise for applications with source resistances greater than 10 kΩ and signal bandwidths greater than 1 kHz. This is illustrated in Figure 40.

OUTPUT CHARACTERISTICS

The AD820/AD822's unique bipolar rail-to-rail output stage swings within 5 mV of the minus supply and 10 mV of the positive supply with no external resistive load. The approximate output saturation resistance is 40 Ω sourcing and 20 Ω sinking. This can be used to estimate output saturation voltage when driving heavier current loads. For instance, when sourcing 5 mA, the saturation voltage to the positive supply rail will be 200 mV, when sinking 5 mA, the saturation voltage to the minus rail will be 100 mV.

The amplifier's open-loop gain characteristic will change as a function of resistive load, as shown in Figures 7 through 10. For load resistances over 20 kΩ, the AD820/AD822's input error voltage is virtually unchanged until the output voltage is driven to 180 mV of either supply.

If the AD820/AD822's output is overdriven so as to saturate either of the output devices, the amplifier will recover within 2 μs of its input returning to the amplifier's linear operating region.

Direct capacitive loads will interact with the amplifier's effective output impedance to form an additional pole in the amplifier's feedback loop, which can cause excessive peaking on the pulse response or loss of stability. Worst case is when the amplifier is used as a unity gain follower. Figure 41 shows the AD820/AD822's pulse response as a unity gain follower driving 350 pF. This amount of overshoot indicates approximately 20 degrees of phase margin—the system is stable, but is nearing the edge. Configurations with less loop gain, and as a result less loop bandwidth, will be much less sensitive to capacitance load effects. Figure 42 is a plot of capacitive load that will result in a 20 degree phase margin versus noise gain for the AD820/AD822. Noise gain is the inverse of the feedback attenuation factor provided by the feedback network in use.

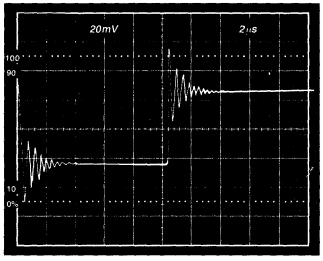

Figure 41. Small Signal Response of AD820/AD822 as Unity Gain Follower Driving 350 pF Capacitive Load

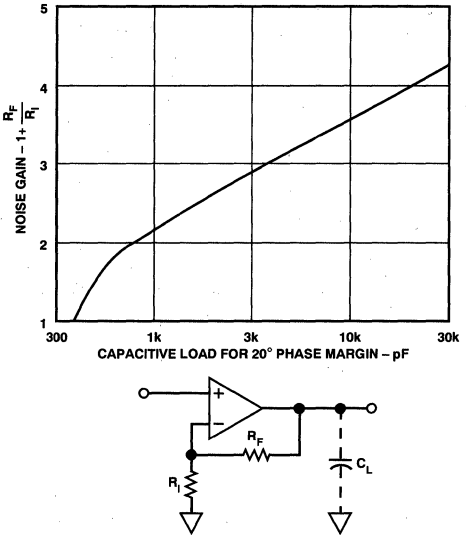

Figure 42. Capacitive Load Tolerance vs. Noise Gain

Figure 43 shows a method for extending capacitance load drive capability for a unity gain follower. With these component values, the circuit will drive 5,000 pF with a 10% overshoot.

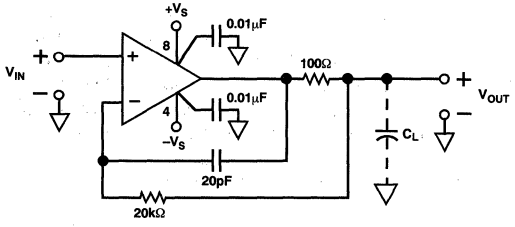

Figure 43. Extending Unity Gain Follower Capacitive Load Capability Beyond 350 pF

OFFSET VOLTAGE ADJUSTMENT

The AD820's offset voltage is low, so external offset voltage nulling is not usually required. Figure 44 shows the recommended technique for AD820's packaged in plastic DIPs. Adjusting offset voltage in this manner will change the offset

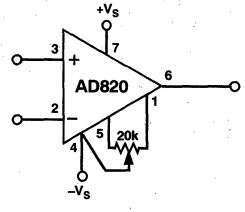

Figure 44. AD820 Offset Null

voltage temperature drift by 4 µV/°C for every millivolt of induced offset. The null pins are not functional for AD820s in the SO-8 "R" package.

APPLICATIONS—AD820

Single Supply Half-Wave and Full-Wave Rectifiers

An AD820 configured as a unity gain follower and operated with a single supply can be used as a simple half-wave rectifier. The AD820's inputs maintain picoamp level input currents even when driven well below the minus supply. The rectifier puts that behavior to good use, maintaining an input impedance of over $10^{11}\Omega$ for input voltages from 1 volt from the positive supply to 20 volts below the negative supply.

The full and half-wave rectifier shown in Figure 45 operates as follows: when V_{IN} is above ground, R1 is bootstrapped through the unity gain follower A1 and the loop of amplifier A2. This forces the inputs of A2 to be equal, thus no current flows through R1 or R2, and the circuit output tracks the input. When V_{IN} is below ground, the output of A1 is forced to ground. The noninverting input of amplifier A2 sees the ground level output of A1, therefore A2 operates as a unity gain inverter. The output at node C is then a full-wave rectified version of the input. Node B is a buffered half-wave rectified version of the input. Input voltages up to ±18 volts can be rectified, depending on the voltage supply used.

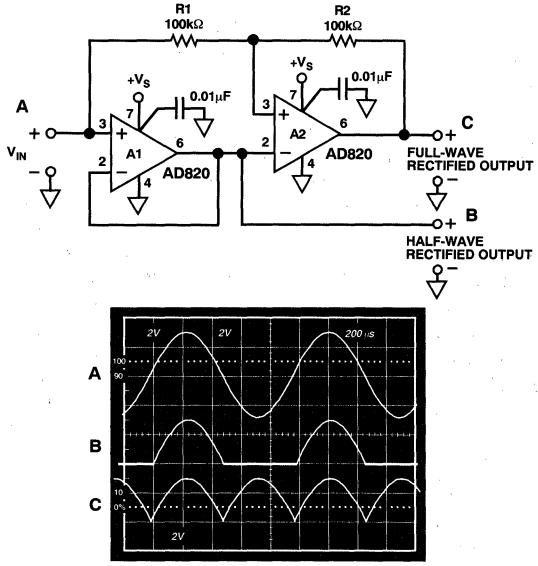

Figure 45. AD820 Single Supply Half- and Full-Wave Rectifier

4.5 Volt Low Dropout, Low Power Reference

The rail-to-rail performance of the AD820 can be used to provide low dropout performance for low power reference circuits powered with a single low voltage supply. Figure 46 shows a 4.5 volt reference using the AD820 and the AD680, a low power 2.5 volt bandgap reference. R2 and R3 set up the required gain of 1.8 to develop the 4.5 volt output. R1 and C2 form a low-pass RC filter to reduce the noise contribution of the AD680.

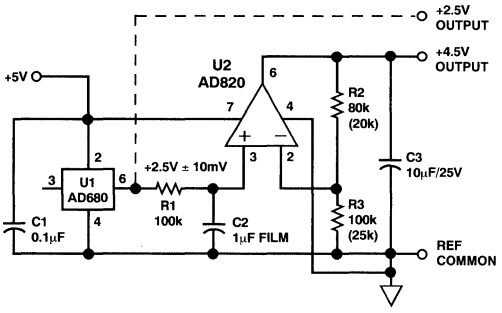

Figure 46. AD820 Single Supply 4.5 Volt Low Dropout Reference

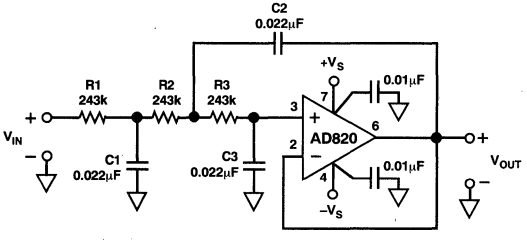
With a 1 mA load, this reference maintains the 4.5 volt output with a supply voltage down to 4.7 volts. The amplitude of the recovery transient for a 1 mA to 10 mA step change in load current is under 20 mV, and settles out in a few microseconds. Output voltage noise is less than 10 µV rms in a 25 kHz noise bandwidth.

Low Power Three-Pole Sallen Key Low-Pass Filter

The AD820's high input impedance makes it a good selection for active filters. High value resistors can be used to construct low frequency filters with capacitors much less than 1 µF. The AD820's picoamp level input currents contribute minimal dc errors.

Figure 47 shows an example, a 10 Hz three-pole Sallen Key Filter. The high value used for R1 minimizes interaction with signal source resistance. Pole placement in this version of the filter minimizes the Q associated with the two-pole section of the filter. This eliminates any peaking of the noise contribution of resistors R1, R2, and R3, thus minimizing the inherent output voltage noise of the filter.



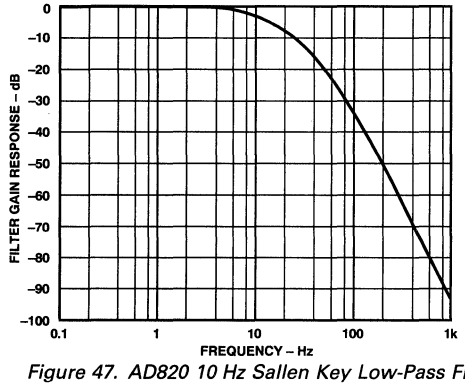


Figure 47. AD820 10 Hz Sallen Key Low-Pass Filter

APPLICATIONS–AD822

Single Supply Voltage-to-Frequency Converter

The circuit shown in Figure 48 uses the AD822 to drive a low power timer, which produces a stable pulse of width t_1. The positive going output pulse is integrated by R1-C1 and used as one input to the AD822, which is connected as a differential integrator. The other input (nonloading) is the unknown voltage, V_{IN}. The AD822 output drives the timer trigger input, closing the overall feedback loop.

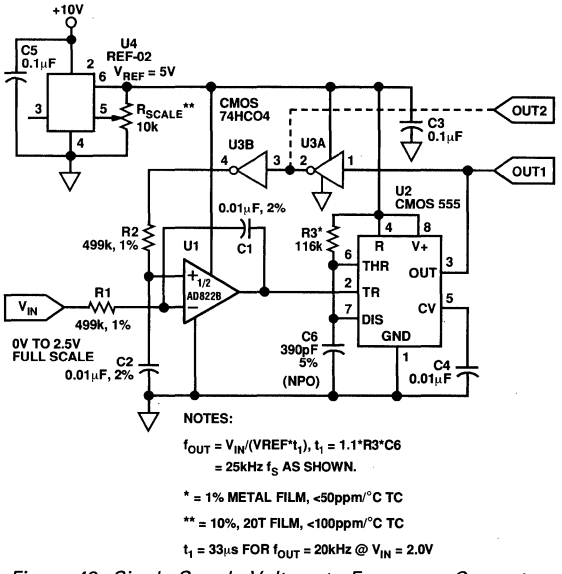

Figure 48. Single Supply Voltage-to-Frequency Converter

Typical AD822 bias currents of 2 pA allow megaohm-range source impedances with negligible dc errors. Linearity errors on the order of 0.01% full scale can be achieved with this circuit. This performance is obtained with a 5 volt single supply which delivers less than 1 mA to the entire circuit.

Single Supply Programmable Gain Instrumentation Amplifier

The AD822 can be configured as a single supply instrumentation amplifier that is able to operate from single supplies down to 3 V, or dual supplies up to ± 15 V. Using only one AD822 rather than three separate op amps, this circuit is cost and power efficient. AD822 FET inputs' 2 pA bias currents minimize offset errors caused by high unbalanced source impedances.

Table I. AD822 In Amp Performance

Parameters	V_S = 3 V, 0 V	V_S = ±5 V
CMRR	74 dB	80 dB
Common-Mode Voltage Range	−0.2 V to +2 V	−5.2 V to +4 V
3 dB BW, G = 10	180 kHz	180 kHz
G = 100	18 kHz	18 kHz
$t_{SETTLING}$ 2 V Step (V_S = 0 V, 3 V)	2 µs	
5 V (V_S = ±5 V)		5 µs
Noise @ f = 1 kHz, G = 10	270 nV/√Hz	270 nV/√Hz
G = 100	2.2 µV/√Hz	2.2 µV/√Hz
I_{SUPPLY} (Total)	1.10 mA	1.15 mA

An array of precision thin-film resistors sets the in amp gain to be either 10 or 100. These resistors are laser-trimmed to ratio match to 0.01%, and have a maximum differential TC of 5 ppm/°C.

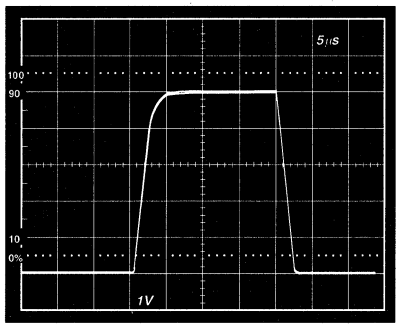

Figure 49a. Pulse Response of In Amp to a 500 mV p-p Input Signal; V_S = +5 V, 0 V; Gain = 10

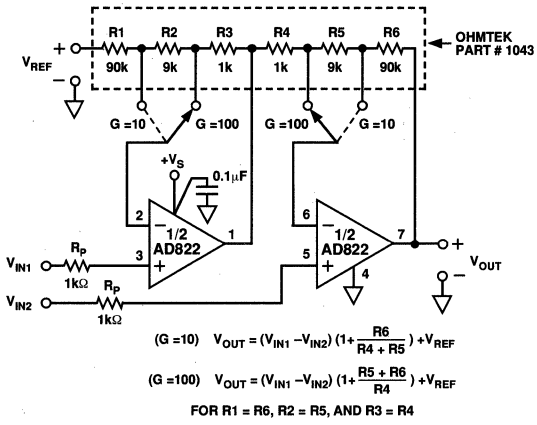

Figure 49b. A Single Supply Programmable Instrumentation Amplifier

3 Volt, Single Supply Stereo Headphone Driver

The AD822 exhibits good current drive and THD+N performance, even at 3 V single supplies. At 1 kHz, total harmonic distortion plus noise (THD+N) equals −62 dB (0.079%) for a 300 mV p-p output signal. This is comparable to other single supply op amps which consume more power and cannot run on 3 V power supplies.

In Figure 50, each channel's input signal is coupled via a 1 µF Mylar capacitor. Resistor dividers set the dc voltage at the noninverting inputs so that the output voltage is midway between the power supplies (+1.5 V). The gain is 1.5. Each half of the AD822 can then be used to drive a headphone channel. A 5 Hz high-pass filter is realized by the 500 µF capacitors and the headphones, which can be modeled as 32 ohm load resistors to ground. This ensures that all signals in the audio frequency range (20 Hz–20 kHz) are delivered to the headphones.

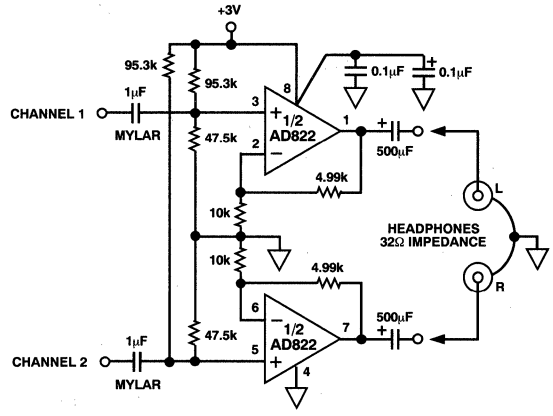

Figure 50. 3 Volt Single Supply Stereo Headphone Driver

Low Dropout Bipolar Bridge Driver

The AD822 can be used for driving a 350 ohm Wheatstone bridge. Figure 51 shows one half of the AD822 being used to buffer the AD589—a 1.235 V low power reference. The output of +4.5 V can be used to drive an A/D converter front end. The other half of the AD822 is configured as a unity-gain inverter, and generates the other bridge input of −4.5 V. Resistors R1 and R2 provide a constant current for bridge excitation. The AD620 low power instrumentation amplifier is used to condition the differential output voltage of the bridge. The gain of the AD620 is programmed using an external resistor R_G, and determined by:

$$G = \frac{49.4\ k\Omega}{R_G} + 1$$

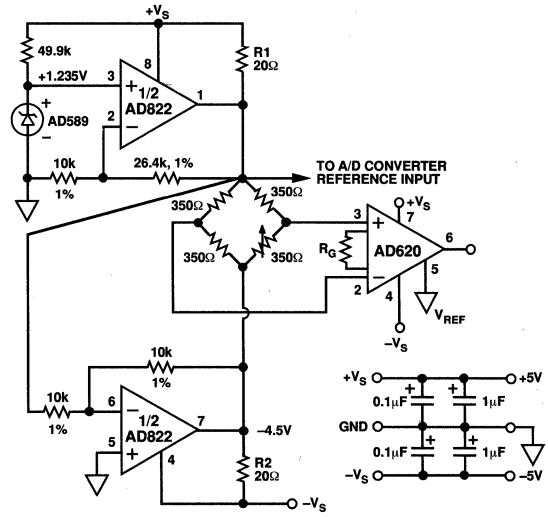

Figure 51. Low Dropout Bipolar Bridge Driver

High Speed, Low Power Dual Operational Amplifier

AD826

FEATURES

High Speed:
- 50 MHz Unity Gain Bandwidth
- 350 V/μs Slew Rate
- 70 ns Settling Time to 0.01%

Low Power:
- 7.5 mA Max Power Supply Current Per Amp

Easy to Use:
- Drives Unlimited Capacitive Loads
- 50 mA Min Output Current Per Amplifier
- Specified for +5 V, ±5 V and ±15 V Operation
- 2.0 V p-p Output Swing into a 150 Ω Load (V_S = +5 V)

Good Video Performance
- Differential Gain & Phase Error of 0.07% & 0.11°

Excellent DC Performance:
- 2.0 mV Max Input Offset Voltage

APPLICATIONS

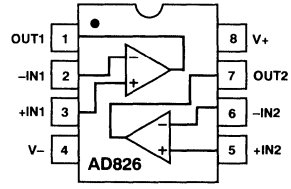
- Unity Gain ADC/DAC Buffer
- Cable Drivers
- 8- and 10-Bit Data Acquisition Systems
- Video Line Driver
- Active Filters

PRODUCT DESCRIPTION

The AD826 is a dual, high speed voltage feedback op amp. It is ideal for use in applications which require unity gain stability and high output drive capability, such as buffering and cable driving. The 50 MHz bandwidth and 350 V/μs slew rate make the AD826 useful in many high speed applications including: video, CATV, copiers, LCDs, image scanners and fax machines.

CONNECTION DIAGRAM

8-Pin Plastic Mini-DIP and SO Package



The AD826 features high output current drive capability of 50 mA min per amp, and is able to drive unlimited capacitive loads. With a low power supply current of 15 mA max for both amplifiers, the AD826 is a true general purpose operational amplifier.

The AD826 is ideal for power sensitive applications such as video cameras and portable instrumentation. The AD826 can operate from a single +5 V supply, while still achieving 25 MHz of bandwidth. Furthermore the AD826 is fully specified from a single +5 V to ±15 V power supplies.

The AD826 excels as an ADC/DAC buffer or active filter in data acquisition systems and achieves a settling time of 70 ns to 0.01%, with a low input offset voltage of 2 mV max. The AD826 is available in small 8-pin plastic mini-DIP and SO packages.

AD826AR	−40°C to +85°C	8-Pin Plastic SOIC	R-8
AD826AR-REEL	−40°C to +85°C	8-Pin Plastic SOIC	R-8

*For outline information see Package Information section.

ESD SUSCEPTIBILITY

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 volts, which readily accumulate on the human body and on test equipment, can discharge without detection. Although the AD826 features proprietary ESD protection circuitry, permanent damage may still occur on these devices if they are subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid any performance degradation or loss of functionality.

THEORY OF OPERATION

The AD826 is a low cost, wide band, high performance dual operational amplifier which can drive heavy capacitive and resistive loads. It also achieves a constant slew rate, bandwidth and settling time over its entire specified temperature range.

The AD826 (Figure 35) consists of a degenerated NPN differential pair driving matched PNPs in a folded-cascode gain stage. The output buffer stage employs emitter followers in a class AB amplifier which delivers the necessary current to the load while maintaining low levels of distortion.

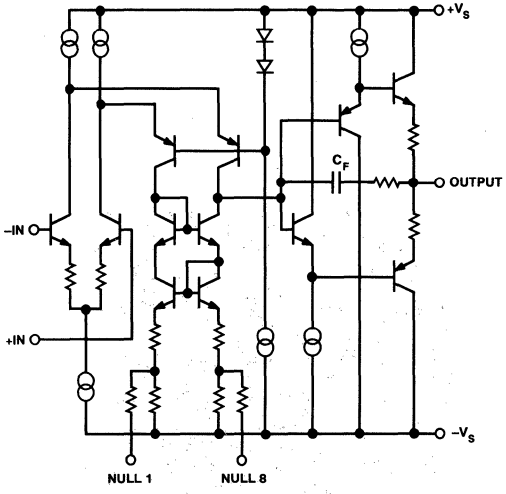

Figure 35. Simplified Schematic

The capacitor, C_F, in the output stage mitigates the effect of capacitive loads. With low capacitive loads, the gain from the compensation node to the output is very close to unity. In this case, C_F is bootstrapped and does not contribute to the overall compensation capacitance of the device. As the capacitive load is increased, a pole is formed with the output impedance of the output stage. This reduces the gain, and therefore, C_F is incompletely bootstrapped. Effectively, some fraction of C_F contributes to the overall compensation capacitance, reducing the unity gain bandwidth. As the load capacitance is further increased, the bandwidth continues to fall, maintaining the stability of the amplifier.

INPUT CONSIDERATIONS

An input protection resistor (R_{IN} in Figure 25) is required in circuits where the input to the AD826 will be subjected to transient or continuous overload voltages exceeding the ±6 V maximum differential limit. This resistor provides protection for the input transistors by limiting their maximum base current.

For high performance circuits, it is recommended that a "balancing" resistor be used to reduce the offset errors caused by bias current flowing through the input and feedback resistors. The balancing resistor equals the parallel combination of R_{IN} and R_F and thus provides a matched impedance at each input terminal. The offset voltage error will then be reduced by more than an order of magnitude.

APPLYING THE AD826

The AD826 is a breakthrough dual amp that delivers precision and speed at low cost with low power consumption. The AD826 offers excellent static and dynamic matching characteristics, combined with the ability to drive heavy resistive and capacitive loads.

As with all high frequency circuits, care should be taken to maintain overall device performance as well as their matching. The following items are presented as general design considerations.

Circuit Board Layout

Input and output runs should be laid out so as to physically isolate them from remaining runs. In addition, the feedback resistor of each amplifier should be placed away from the feedback resistor of the other amplifier, since this greatly reduces inter-amp coupling.

Choosing Feedback and Gain Resistors

In order to prevent the stray capacitance present at each amplifier's summing junction from limiting its performance, the feedback resistors should be ≤ 1 kΩ. Since the summing junction capacitance may cause peaking, a small capacitor (1-5 pF) may be paralleled with Rf to neutralize this effect. Finally, sockets should be avoided, because of their tendency to increase interlead capacitance.

Power Supply Bypassing

Proper power supply decoupling is critical to preserve the integrity of high frequency signals. In carefully laid out designs, decoupling capacitors should be placed in close proximity to the supply pins, while their lead lengths should be kept to a minimum. These measures greatly reduce undesired inductive effects on the amplifier's response.

Though two 0.1 μF capacitors will typically be effective in decoupling the supplies, several capacitors of different values can be paralleled to cover a wider frequency range.

±SINGLE SUPPLY OPERATION

An exciting feature of the AD826 is its ability to perform well in a single supply configuration (see Figure 37). The AD826 is ideally suited for applications that require low power dissipation and high output current and those which need to drive large capacitive loads, such as high speed buffering and instrumentation.

Referring to Figure 36, careful consideration should be given to the proper selection of component values. The choices for this particular circuit are: (R1+ R3)‖R2 combine with C1 to form a low frequency corner of approximately 30 Hz.

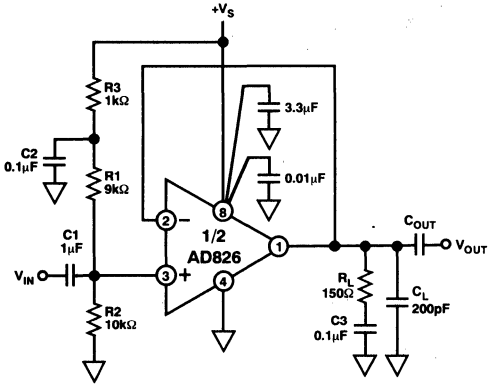

Figure 36. Single Supply Amplifier Configuration

R3 and C2 reduce the effect of the power supply changes on the output by low pass filtering with a corner at $\frac{1}{2\pi R_3 C_2}$.

The values for R_L and C_L were chosen to demonstrate the AD826's exceptional output drive capability. In this configuration, the output is centered around 2.5 V. In order to eliminate the static dc current associated with this level, C3 was inserted in series with R_L.

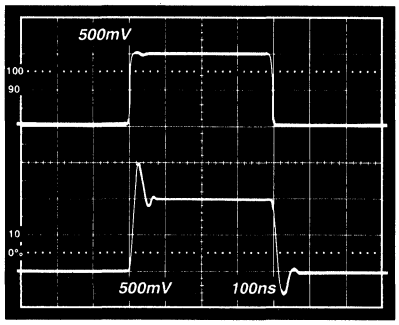

Figure 37. Single Supply Pulse Response, G = +1, R_L = 150 Ω, C_L = 200 pF

9

PARALLEL AMPS PROVIDE 100 mA TO LOAD

By taking advantage of the superior matching characteristics of the AD826, enhanced performance can easily be achieved by employing the circuit in Figure 38. Here, two identical cells are paralleled to obtain even higher load driving capability than that of a single amplifier (100 mA min guaranteed). R1 and R2 are included to limit current flow between amplifier outputs that would arise in the presence of any residual mismatch.

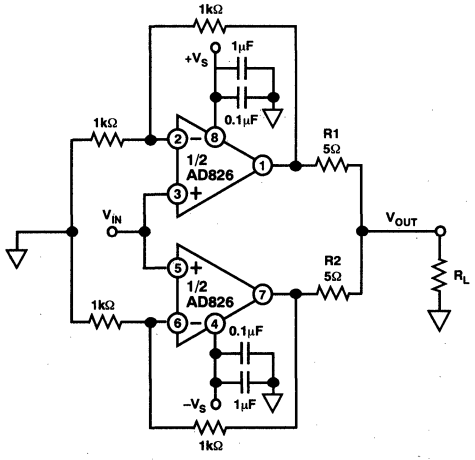

Figure 38. Parallel Amp Configuration

SINGLE-ENDED TO DIFFERENTIAL LINE DRIVER

Outstanding CMRR (>80 dB @ 5 MHz), high bandwidth, wide supply voltage range, and the ability to drive heavy loads, make the AD826 an ideal choice for many line driving applications. In this application, the AD830 high speed video difference amp serves as the differential line receiver on the end of a back terminated, 50 ft., twisted-pair transmission line (see Figure 40). The overall system is configured in a gain of +1 and has a −3 dB bandwidth of 14 MHz. Figure 39 is the pulse response with a 2 V p-p, 1 MHz signal input.

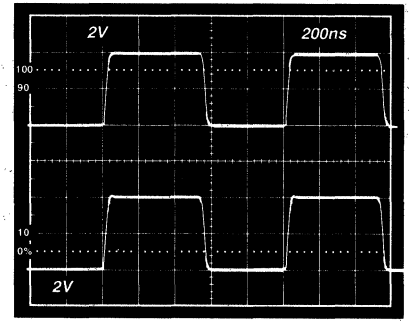

Figure 39. Pulse Response

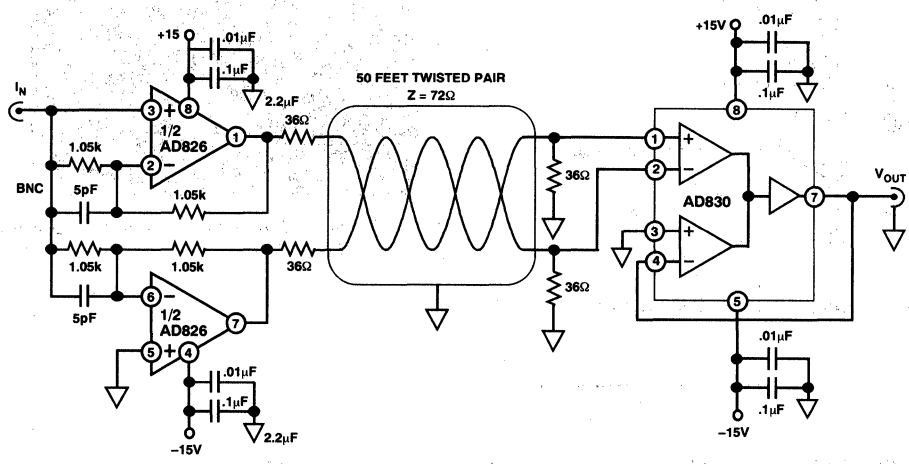

Figure 40. Differential Line Driver

LOW DISTORTION LINE DRIVER

The AD826 can quickly be turned into a powerful, low distortion line driver (see Figure 41). In this arrangement the AD826 can comfortably drive a 75 Ω back-terminated cable, with a 5 MHz, 2 V p-p input; all of this while achieving the harmonic distortion performance outlined in the following table.

Configuration	2nd Harmonic
1. No Load	−78.5 dBm
2. 150 Ω R_L Only	−63.8 dBm
3. 150 Ω R_L 7.5 Ω R_C	−70.4 dBm

In this application one half of the AD826 operates at a gain of 2.1 and supplies the current to the load, while the other provides the overall system gain of 2. This is important for two reasons: the first is to keep the bandwidth of both amplifiers the same, and the second is to preserve the AD826's ability to operate from low supply voltages. R_C varies with the load and must be chosen to satisfy the following equation:

$$R_C = MR_L,$$

where M is defined by $[(M+1)\ G_S = G_D]$ and G_D = Driver's Gain, G_S = System Gain.

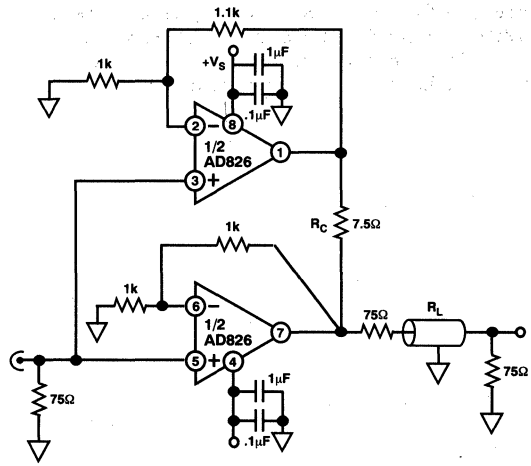

Figure 41. Low Distortion Amplifier

HIGH PERFORMANCE ADC BUFFER

Figure 42 is a schematic of a 12-bit high speed analog-to-digital converter. The AD826 dual op amp takes a single ended input and drives the AD872 A/D converter differentially, thus reducing 2nd harmonic distortion. Figure 43 is a FFT of a 1 MHz input, sampled at 10 MHz with a THD of −78 dB. The AD826 can be used to amplify low level signals so that the entire range of the converter is used. The ability of the AD826 to perform on a ±5 volt supply or even with a single 5 volts combined with its rapid settling time and ability to deliver high current to complicated loads make it a very good flash A/D converter buffer as well as a very useful general purpose building block.

High Speed, Low Power Dual Op Amp

AD827

FEATURES

HIGH SPEED
50 MHz Unity Gain Stable Operation
300 V/μs Slew Rate
120 ns Settling Time
Drives Unlimited Capacitive Loads

EXCELLENT VIDEO PERFORMANCE
0.04% Differential Gain @ 4.4 MHz
0.19° Differential Phase @ 4.4 MHz

GOOD DC PERFORMANCE
2 mV max Input Offset Voltage
15 μV/°C Input Offset Voltage Drift
Available in Tape and Reel in Accordance with EIA-481A Standard

LOW POWER
Only 10 mA Total Supply Current for Both Amplifiers ±5 V to ±15 V Supplies

PRODUCT DESCRIPTION

The AD827 is a dual version of Analog Devices' industry-standard AD847 op amp. Like the AD847, it provides high speed, low power performance at low cost. The AD827 achieves a 300 V/μs slew rate and 50 MHz unity-gain bandwidth while consuming only 100 mW when operating from ±5 volt power supplies. Performance is specified for operation using ±5 V to ±15 V power supplies.

The AD827 offers an open-loop gain of 3,500 V/V into 500 Ω loads. It also features a low input voltage noise of 15 nV/$\sqrt{\text{Hz}}$, and a low input offset voltage of 2 mV maximum. Common-mode rejection ratio is a minimum of 80 dB. Power supply rejection ratio is maintained at better than 20 dB with input frequencies as high as 1 MHz, thus minimizing noise feedthrough from switching power supplies.

The AD827 is also ideal for use in demanding video applications, driving coaxial cables with less than 0.04% differential gain and 0.19° differential phase errors for 643 mV p–p into a 75 Ω reverse terminated cable.

The AD827 is also useful in multichannel, high speed data conversion systems where its fast (120 ns to 0.1%) settling time is of importance. In such applications, the AD827 serves as an input buffer for 8-bit to 10-bit A/D converters and as an output amplifier for high speed D/A converters.

APPLICATION HIGHLIGHTS

1. Performance is fully specified for operation using ±5 V to ±15 V supplies.
2. A 0.04% differential gain and 0.19° differential phase error at the 4.4 MHz color subcarrier frequency, together with its low cost, make it ideal for many video applications.
3. The AD827 can drive unlimited capacitive loads, while its 30 mA output current allows 50 Ω and 75 Ω reverse-terminated loads to be driven.
4. The AD827's 50 MHz unity-gain bandwidth makes it an ideal candidate for multistage active filters.
5. The AD827 is available in 8-pin plastic mini-DIP and cerdip, 20-pin LCC, and 16-pin SOIC packages. Chips and MIL-STD-883B processing are also available.

Dual, Low Power Video Op Amp

AD828

FEATURES

Excellent Video Performance
- Differential Gain & Phase Error of 0.01% & 0.05°

High Speed
- 130 MHz 3 dB Bandwidth (G = +2)
- 450 V/μs Slew Rate
- 80 ns Settling Time to 0.01%

Low Power
- 15 mA Max Power Supply Current

High Output Drive Capability:
- 50 mA Minimum Output Current per Amplifier
- Ideal for Driving Back Terminated Cables

Flexible Power Supply
- Specified for +5 V, ±5 V and ±15 V Operation
- ±3.2 V min Output Swing into a 150 Ω Load (V_S = ±5 V)

Excellent DC Performance
- 2.0 mV Input Offset Voltage

Available in 8-Pin SOIC and 8-Pin Plastic Mini-DIP

FUNCTIONAL BLOCK DIAGRAM

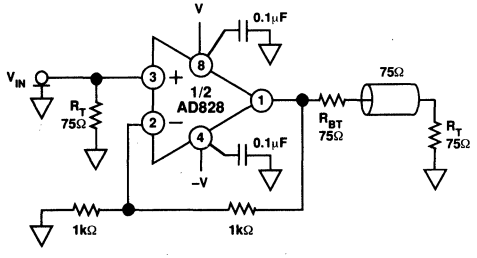
PRODUCT DESCRIPTION

The AD828 is a low cost, dual video op amp optimized for use in video applications which require gains of +2 or greater and high output drive capability, such as cable driving. Due to its low power and single supply functionality, along with excellent differential gain and phase errors, the AD828 is ideal for power sensitive applications such as video cameras and professional video equipment.

With video specs like 0.1 dB flatness to 40 MHz and low differential gain and phase errors of 0.01% and 0.05°, along with 50 mA of output current per amplifier, the AD828 is an excellent choice for any video application. The 130 MHz gain bandwidth and 450 V/μs slew rate make the AD828 useful in many high speed applications including: video monitors, CATV, color copiers, image scanners and fax machines.



AD828 Video Line Driver

The AD828 is fully specified for operation with a single +5 V power supply and with dual supplies from ±5 V to ±15 V. This power supply flexibility, coupled with a very low supply current of 15 mA and excellent ac characteristics under all power supply conditions, make the AD828 the ideal choice for many demanding yet power sensitive applications.

The AD828 is a voltage feedback op amp which excels as a gain stage (gains >+2) or active filter in high speed and video systems and achieves a settling time of 45 ns to 0.1%, with a low input offset voltage of 2 mV max.

The AD828 is available in low cost, small 8-pin plastic mini-DIP and SOIC packages.

Maximum Power Dissipation vs. Temperature for Different Package Types

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the AD828 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

THEORY OF OPERATION

The AD828 is a low cost, dual video operational amplifier designed to excel in high performance, high output current video applications.

The AD828 (Figure 37) consists of a degenerated NPN differential pair driving matched PNPs in a folded-cascode gain stage. The output buffer stage employs emitter followers in a class AB amplifier that delivers the necessary current to the load while maintaining low levels of distortion.

The AD828 will drive terminated cables and capacitive loads of 10 pF or less. As the closed-loop gain is increased, the AD828 will drive heavier cap loads without oscillating.

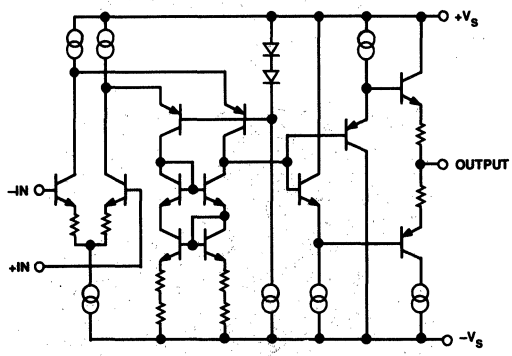

Figure 37. AD828 Simplified Schematic

INPUT CONSIDERATIONS

An input protection resistor (R_{IN} in Figure 31) is required in circuits where the input to the AD828 will be subjected to transient or continuous overload voltages exceeding the ±6 V maximum differential limit. This resistor provides protection for the input transistors by limiting their maximum base current.

For high performance circuits, it is recommended that a "balancing" resistor be used to reduce the offset errors caused by bias current flowing through the input and feedback resistors. The balancing resistor equals the parallel combination of R_{IN} and R_F and thus provides a matched impedance at each input terminal. The offset voltage error will then be reduced by more than an order of magnitude.

APPLYING THE AD828

The AD828 is a breakthrough dual amp that delivers precision and speed at low cost with low power consumption. The AD828 offers excellent static and dynamic matching characteristics, combined with the ability to drive heavy resistive loads.

As with all high frequency circuits, care should be taken to maintain overall device performance as well as their matching. The following items are presented as general design considerations.

Circuit Board Layout

Input and output runs should be laid out so as to physically isolate them from remaining runs. In addition, the feedback resistor of each amplifier should be placed away from the feedback resistor of the other amplifier, since this greatly reduces interamp coupling.

Choosing Feedback and Gain Resistors

In order to prevent the stray capacitance present at each amplifier's summing junction from limiting its performance, the feedback resistors should be ≤ 1 kΩ. Since the summing junction capacitance may cause peaking, a small capacitor (1–5 pF) may be paralleled with Rf to neutralize this effect. Finally, sockets should be avoided, because of their tendency to increase interlead capacitance.

Power Supply Bypassing

Proper power supply decoupling is critical to preserve the integrity of high frequency signals. In carefully laid out designs, decoupling capacitors should be placed in close proximity to the supply pins, while their lead lengths should be kept to a minimum. These measures greatly reduce undesired inductive effects on the amplifier's response.

Though two 0.1 μF capacitors will typically be effective in decoupling the supplies, several capacitors of different values can be paralleled to cover a wider frequency range.

PARALLEL AMPS PROVIDE 100 mA TO LOAD

By taking advantage of the superior matching characteristics of the AD828, enhanced performance can easily be achieved by employing the circuit in Figure 38. Here, two identical cells are paralleled to obtain even higher load driving capability than that of a single amplifier (100 mA min guaranteed). R1 and R2 are included to limit current flow between amplifier outputs that would arise in the presence of any residual mismatch.

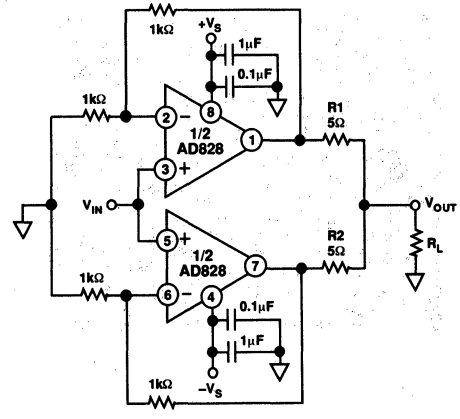

Figure 38. Parallel Amp Configuration

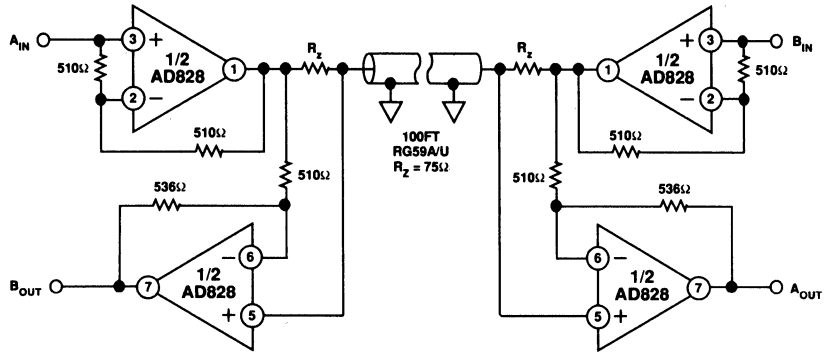

Figure 39. Bidirectional Transmission CKT

Full-Duplex Transmission

Superior load handling capability (50 mA min/amp), high bandwidth, wide supply voltage range and excellent crosstalk rejection makes the AD828 an ideal choice even for the most demanding high speed transmission applications.

The schematic below shows a pair of AD828s configured to drive 100 feet of coaxial cable in a full-duplex fashion.

Two different NTSC video signals are simultaneously applied at A_{IN} and B_{IN} and are recovered at A_{OUT} and B_{OUT}, respectively. This situation is illustrated in Figures 40 and 41. These pictures clearly show that each input signal appears undisturbed at its output, while the unwanted signal is eliminated at either receiver.

The transmitters operate as followers, while the receivers' gain is chosen to take full advantage of the AD828's unparalled CMRR. (In practice this gain is adjusted slightly from its theoretical value to compensate for cable nonidealities and losses.) R_Z is chosen to match the characteristic impedance of the cable employed.

Finally, although a coaxial cable was used, the same topology applies unmodified to a variety of cables (such, as twisted pairs often used in telephony).

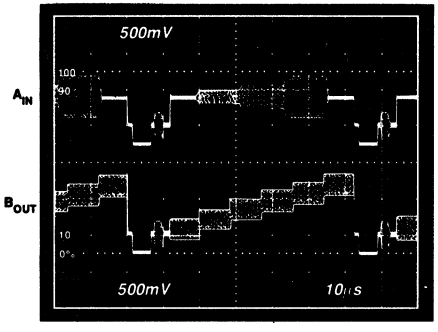

Figure 40. A Transmission/B Reception

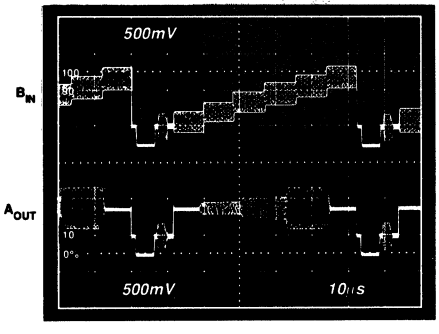

Figure 41. B Transmission/A Reception

A High Performance Video Line Driver

The buffer circuit shown in Figure 42 will drive a back-terminated 75 Ω video line to standard video levels (1 V p-p) with 0.1 dB gain flatness to 40 MHz with only 0.05° and 0.01% differential phase and gain at the 3.58 MHz NTSC subcarrier frequency. This level of performance, which meets the requirements for high-definition video displays and test equipment, is achieved using only 7 mA quiescent current/amplifier.

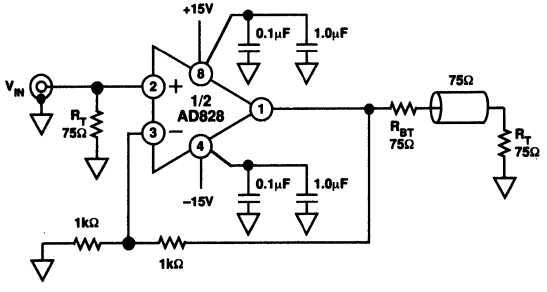

Figure 42. Video Line Driver

LOW DISTORTION LINE DRIVER

The AD828 can quickly be turned into a powerful, low distortion line driver (see Figure 43). In this arrangement the AD828 can comfortably drive a 75 Ω back-terminated cable, with a 5 MHz, 2 V p-p input; all of this while achieving the harmonic distortion performance outlined in the following table.

Configuration	2nd Harmonic
1. No Load	−78.5 dBm
2. 150 Ω R_L Only	−63.8 dBm
3. 150 Ω R_L 7.5 Ω R_C	−70.4 dBm

In this application one half of the AD828 operates at a gain of 2.1 and supplies the current to the load, while the other provides the overall system gain of 2. This is important for two reasons: the first is to keep the bandwidth of both amplifiers the same, and the second is to preserve the AD828's ability to operate from low supply voltage. R_C varies with the load and must be chosen to satisfy the following equation:

$$R_C = MR_L,$$

where M is defined by $[(M+1)\ G_S = G_D]$ and G_D = Driver's Gain, G_S = System Gain.

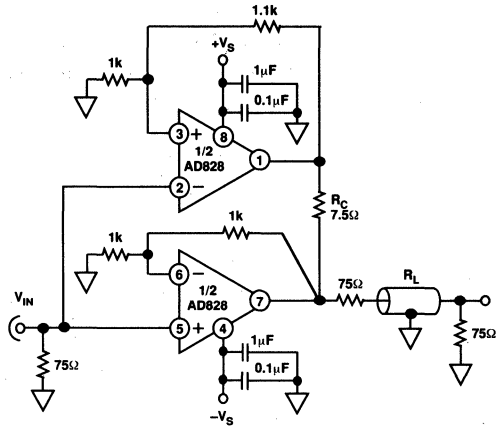

Figure 43. Low Distortion Amplifier

High Speed, Low Noise Video Op Amp

AD829

FEATURES

High Speed
- 120 MHz Bandwidth, Gain = −1
- 230 V/μs Slew Rate
- 90 ns Settling Time to 0.1%

Ideal for Video Applications
- 0.02% Differential Gain
- 0.04° Differential Phase

Low Noise
- 1.7 nV/$\sqrt{Hz}$ Input Voltage Noise
- 1.5 pA/$\sqrt{Hz}$ Input Current Noise

Excellent DC Precision
- 1 mV max Input Offset Voltage (Over Temp)
- 0.3 μV/°C Input Offset Drift

Flexible Operation
- Specified for ±5 V to ±15 V Operation
- ±3 V Output Swing into a 150 Ω Load
- External Compensation for Gains 1 to 20
- 5 mA Supply Current

Available in Tape and Reel in Accordance with EIA-481A Standard

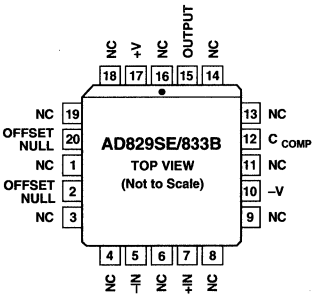
20-Pin LCC Pinout



NC = NO CONNECT

PRODUCT DESCRIPTION

The AD829 is a low noise (1.7 nV/$\sqrt{Hz}$), high speed op amp with custom compensation that provides the user with gains from ±1 to ±20 while maintaining a bandwidth greater than 50 MHz. The AD829's 0.04° differential phase and 0.02% differential gain performance at 3.58 MHz and 4.43 MHz, driving reverse-terminated 50 Ω or 75 Ω cables, makes it ideally suited for professional video applications. The AD829 achieves its 230 V/μs uncompensated slew rate and 750 MHz gain bandwidth product while requiring only 5 mA of current from the power supplies.

The AD829's external compensation pin gives it exceptional versatility. For example, compensation can be selected to optimize the bandwidth for a given load and power supply voltage. As a gain-of-two line driver, the −3 dB bandwidth can be increased to 95 MHz at the expense of 1 dB of peaking. In addition, the AD829's output can also be clamped at its external compensation pin.

The AD829 has excellent dc performance. It offers a minimum open-loop gain of 30 V/mV into loads as low as 500 Ω, low input voltage noise of 1.7 nV/$\sqrt{Hz}$, and a low input offset voltage of 1 mV maximum. Common-mode rejection and power supply rejection ratios are both 120 dB.

The AD829 is also useful in multichannel, high speed data conversion where its fast (90 ns to 0.1%) settling time is of importance. In such applications, the AD829 serves as an input buffer for 8-to-10-bit A/D converters and as an output I/V converter for high speed D/A converters.

The AD829 provides many of the same advantages that a transimpedance amplifier offers, while operating as a traditional voltage feedback amplifier. A bandwidth greater than 50 MHz can be maintained for a range of gains by changing the external compensation capacitor. The AD829 and the transimpedance amplifier are both unity gain stable and provide similar voltage noise performance (1.7 nV/$\sqrt{Hz}$). However, the current noise of the AD829 (1.5 pA/$\sqrt{Hz}$) is less than 10% of the noise of transimpedance amps. Furthermore, the inputs of the AD829 are symmetrical.

PRODUCT HIGHLIGHTS

1. Input voltage noise of 2 nV/$\sqrt{Hz}$, current noise of 1.5 pA/$\sqrt{Hz}$ and 50 MHz bandwidth, for gains of 1 to 20, make the AD829 an ideal preamp.
2. Differential phase error of 0.04° and a 0.02% differential gain error, at the 3.58 MHz NTSC and 4.43 MHz PAL and SECAM color subcarrier frequencies, make it an outstanding video performer for driving reverse-terminated 50 Ω and 75 Ω cables to ±1 V (at their terminated end).
3. The AD829 can drive heavy capacitive loads.
4. Performance is fully specified for operation from ±5 V to ±15 V supplies.
5. Available in plastic, cerdip, and small outline packages. Chips and MIL-STD-883B parts are also available.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

NOTES
[1]Stresses above those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. This is a stress rating only and functional operation of the device at these or any other conditions above those indicated in the operational section of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.
[2]Maximum internal power dissipation is specified so that T_J does not exceed +175°C at an ambient temperature of +25°C.
Thermal characteristics:
8-pin plastic package: θ_{JA} = 100°C/watt (derate at 8.7 mW/°C)
8-pin cerdip package: θ_{JA} = 110°C/watt (derate at 8.7 mW/°C)
20-pin LCC package: θ_{JA} = 150°C/watt
8-pin small outline package: θ_{JA} = 155°C/watt (derate at 6 mW/°C).
[3]If the differential voltage exceeds 6 volts, external series protection resistors should be added to limit the input current.

METALIZATION PHOTO

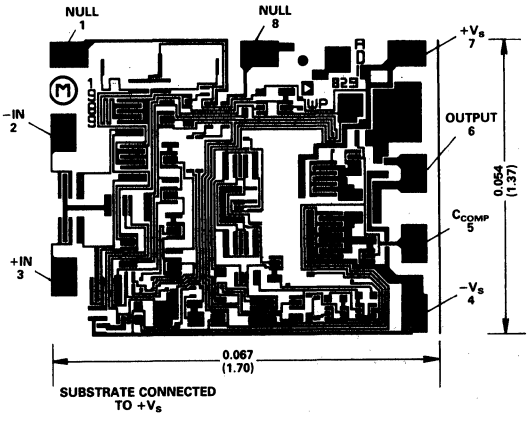
Dimensions shown in inches and (mm).



ESD SUSCEPTIBILITY

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 volts, which readily accumulate on the human body and on test equipment, can discharge without detection. Although the AD829 features proprietary ESD protection circuitry, permanent damage may still occur on these devices if they are subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid any performance degradation or loss of functionality.

High Speed, Video Difference Amplifier

AD830

FEATURES

Differential Amplification
- Wide Common-Mode Voltage Range: +12.8 V, −12 V
- Differential Voltage Range: ±2 V
- High CMRR: 60 dB @ 4 MHz
- Built-in Differential Clipping Level: ±2.3 V

Fast Dynamic Performance
- 85 MHz Unity Gain Bandwidth
- 35 ns Settling Time to 0.1%
- 360 V/μs Slew Rate

Symmetrical Dynamic Response

Excellent Video Specifications
- Differential Gain Error: 0.06%
- Differential Phase Error: 0.08°
- 15 MHz (0.1 dB) Bandwidth

Flexible Operation
- High Output Drive of ±50 mA min
- Specified with Both ±5 V and ±15 V Supplies

Low Distortion: THD = −72 dB @ 4 MHz

Excellent DC Performance: 3 mV max Input Offset Voltage

APPLICATIONS

Differential Line Receiver

High Speed Level Shifter

High Speed In-Amp

Differential to Single Ended Conversion

Resistorless Summation and Subtraction

High Speed A/D Driver

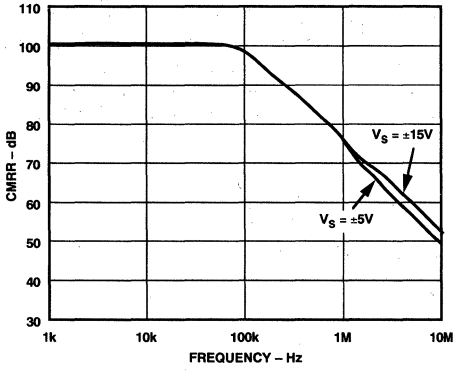
PRODUCT DESCRIPTION

The AD830 is a wideband, differencing amplifier designed for use at video frequencies but also useful in many other applications. It accurately amplifies a fully differential signal at the input and produces an output voltage referred to a user-chosen level. The undesired common-mode signal is rejected, even at high frequencies. High impedance inputs ease interfacing to finite source impedances and thus preserve the excellent common-mode rejection. In many respects, it offers significant improvements over discrete difference amplifier approaches, in particular in high frequency common-mode rejection.

The wide common-mode and differential-voltage range of the AD830 make it particularly useful and flexible in level shifting applications, but at lower power dissipation than discrete solutions. Low distortion is preserved over the many possible differential and common-mode voltages at the input and output.

Good gain flatness and excellent differential gain of 0.06% and phase of 0.08° make the AD830 suitable for many video system applications. Furthermore, the AD830 is suited for general purpose signal processing from dc to 10 MHz.



Common-Mode Rejection Ratio vs. Frequency

NOTES
[1]Stresses above those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. This is a stress rating only and functional operation of the device at these or any other conditions above those indicated in the operational section of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.
[2]8-Pin Plastic Package: θ_{JA} = 90°C/Watt
8-Pin SOIC Package: θ_{JA} = 155°C/Watt
8-Pin Cerdip Package: θ_{JA} = 110°C/Watt

MAXIMUM POWER DISSIPATION

The maximum power that can be safely dissipated by the AD830 is limited by the associated rise in junction temperature. For the plastic packages, the maximum safe junction temperature is 145°C. For the cerdip, the maximum junction temperature is 175°C. If these maximums are exceeded momentarily, proper circuit operation will be restored as soon as the die temperature is reduced. Leaving the AD830 in the "overheated" condition for an extended period can result in permanent damage to the device. To ensure proper operation, it is important to observe the recommended derating curves.

While the AD830 output is internally short circuit protected, this may not be sufficient to guarantee that the maximum junction temperature is not exceeded under all conditions. If the output is shorted to a supply rail for an extended period, then the amplifier may be permanently destroyed.

ESD SUSCEPTIBILITY

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 volts, which readily accumulate on the human body and on test equipment, can discharge without detection. Although the AD830 features proprietary ESD protection circuitry, permanent damage may still occur on these devices if they are subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid any performance degradation or loss of functionality.

TRADITIONAL DIFFERENTIAL AMPLIFICATION

In the past, when differential amplification was needed to reject common-mode signals superimposed with a desired signal; most often the solution used was the classic op amp based difference amplifier shown in Figure 19. The basic function $V_O = V_1 - V_2$ is simply achieved, but the overall performance is poor and the circuit possesses many serious problems that make it difficult to realize a robust design with moderate to high levels of performance.

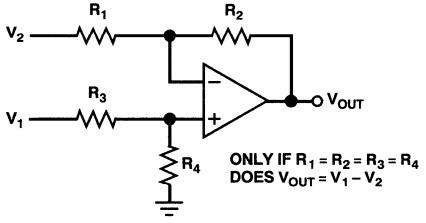

Figure 19. Op Amp Based Difference Amplifier

PROBLEMS WITH THE OP AMP BASED APPROACH

- Low Common-Mode Rejection Ratio (CMRR)
- Low Impedance Inputs
- CMRR Highly Sensitive to the Value of Source R
- Different Input Impedance for the + and − Input
- Poor High Frequency CMRR
- Requires Very Highly Matched Resistors R_1–R_4 to Achieve High CMRR
- Halves the Bandwidth of the Op Amp
- High Power Dissipation in the Resistors for Large Common-Mode Voltage

AD830 FOR DIFFERENTIAL AMPLIFICATION

The AD830 amplifier was specifically developed to solve the listed problems with the discrete difference amplifier approach. Its topology, discussed in detail in a later section, by design acts as a difference amplifier. The circuit of Figure 20 shows how simply the AD830 is configured to produce the difference of two signals V_1 and V_2, in which the applied differential signal is exactly reproduced at the output relative to a separate output common. Any common-mode voltage present at the input is removed by the AD830.

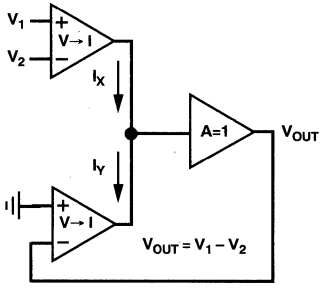

Figure 20. AD830 as a Difference Amplifier

ADVANTAGEOUS PROPERTIES OF THE AD830

- High Common-Mode Rejection Ratio (CMRR)
- High Impedance Inputs
- Symmetrical Dynamic Response for +1 and −1 Gain
- Low Sensitivity to the Value of Source R
- Equal Input Impedance for the + and − Input
- Excellent High Frequency CMRR
- No Halving of the Bandwidth
- Constant Power Distortion vs. Common-Mode Voltage
- Highly Matched Resistors Not Needed

9

UNDERSTANDING THE AD830 TOPOLOGY

The AD830 represents Analog Devices' first amplifier product to embody a powerful alternative amplifier topology. Referred to as active feedback, the topology used in the AD830 provides inherent advantages in the handling of differential signals, differing system commons, level shifting and low distortion, high frequency amplification. In addition, it makes possible the implementation of many functions not realizable with single op amp circuits or is superior to op amp based equivalent circuits. With this in mind, it is important to understand the internal structure of the AD830.

The topology, reduced to its elemental form, is shown below in Figure 21. Nonideal effects such as nonlinearity, bias currents and limited full scale are omitted from this model for simplicity, but are discussed later. The key feature of this topology is the use of two, identical voltage-to-current converters, G_M, that make up input and feedback signal interfaces. They are labeled with inputs V_X and V_Y, respectively. These voltage to current converters possess fully differential inputs, high linearity, high input impedance and wide voltage range operation. This enables the part to handle large amplitude differential signals; they also provide high common-mode rejection, low distortion and negligible loading on the source. The label, G_M, is meant to convey that the transconductance is a large signal quantity, unlike in the front-end of most op amps. The two G_M stage current outputs I_X and I_Y, sum together at a high impedance node which is characterized by an equivalent resistance and capacitance connected to an "ac common." A unity voltage gain stage follows the high impedance node to provide buffering from loads. Relative to either input, the open loop gain, A_{OL}, is set by the transconductance, G_M, working into the resistance, R_P; $A_{OL} = G_M \times R_P$. The unity gain frequency $\omega_{0\ dB}$ for the open loop gain is established by the transconductance, G_M, working into the capacitance, C_C; $\omega_{0\ dB} = G_M/C_C$. The open loop description of the AD830 is shown below for completeness.

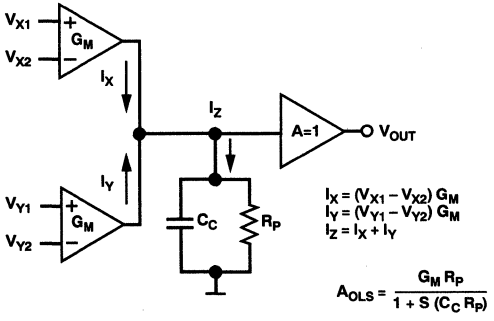

Figure 21. Topology Diagram

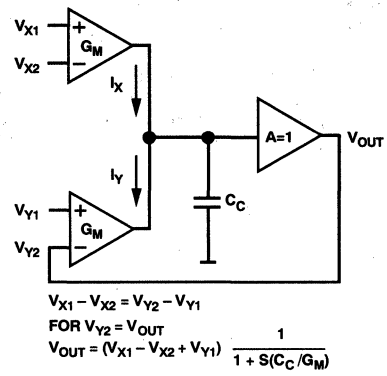

Figure 22. Closed-Loop Connection

Precise amplification is accomplished through closed-loop operation of this topology. Voltage feedback is implemented via the Y G_M stage in which where the output is connected to the $-Y$ input for negative feedback as shown in Figure 22. An input signal is applied across the X G_M stage, either fully differentially or single-ended referred to common. It produces a current signal which is summed at the high impedance node with the output current from the Y G_M stage. Negative feedback nulls this sum to a small error current necessary to develop the output voltage at the high impedance node. The error current is usually negligible, so the null condition essentially forces the Y G_M output stage current to exactly equal the X G_M output current. Since the two transconductances are identical, the differential voltage across the Y inputs equals the negative of the differential voltage across the X input; $V_Y = -V_X$ or more precisely $V_{Y2}–V_{Y1} = V_{X1}–V_{X2}$. This simple relation provides the basis to easily analyze any function possible to synthesize with the AD830, including any feedback situation.

The bandwidth of the circuit is defined by the G_M and the capacitor C_C. The highly linear G_M stages give the amplifier a single pole response, excluding the output amplifier and loading effects. *It is important to note that the bandwidth and general dynamic behavior is symmetrical (identical) for the noninverting and the inverting connections of the AD830.* In addition, the input impedance and CMRR are the same for either connections. This is very advantageous and unlike in a voltage or current feedback amplifier, where there is a distinct difference in performance between the inverting and noninverting gain. The practical importance of this cannot be overemphasized and is a key feature offered by the AD830 amplifier topology.

INTERFACING THE INPUT

Common-Mode Voltage Range

The common-mode range of the AD830 is defined by the amplitude of the differential input signal and the supply voltage. The general definition of common-mode voltage, V_{CM}, is usually applied to a symmetrical differential signal centered about a particular voltage as illustrated by the diagram in Figure 23. This is the meaning implied here for common-mode voltage. The internal circuitry establishes the maximum allowable voltage on the input or feedback pins for a given supply voltage. This constraint and the differential input voltage sets the common-mode voltage limit. Figure 24 shows a curve of the common-mode voltage range vs. differential voltage for three supply voltage settings.

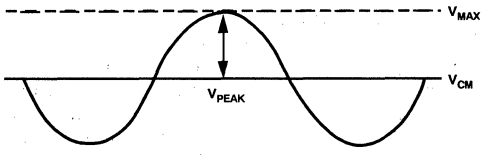

Figure 23. Common-Mode Definition

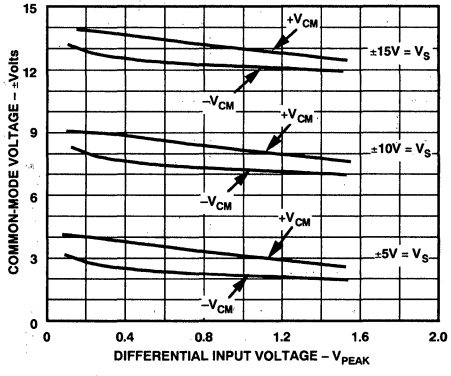

Figure 24. Input Common-Mode Voltage Range vs. Differential Input Voltage

Differential Voltage Range

The maximum applied differential voltage is limited by the clipping range of the input stages. This is nominally set at 2.4 volts magnitude and depicted in the crossplot (X-Y) photo of Figure 25. The useful linear range of the input stages is set at 2 volts, but is actually a function of the distortion required for a particular application. The distortion increases for larger differential input voltages. A plot of relative distortion versus input differential voltage is shown in Figures 8 and 11 in the Typical Characteristics section. The distortion characteristics could impose a secondary limit to the differential input voltage for high accuracy applications.

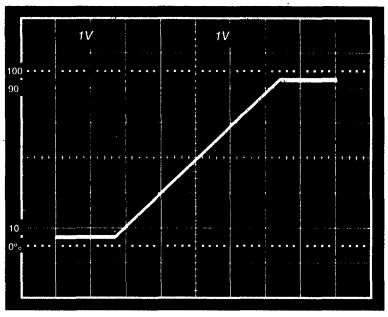

Figure 25. Clipping Behavior

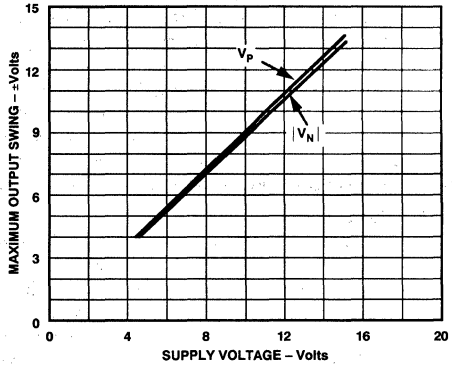

Figure 26. Maximum Output Swing vs. Supply

Choice of Polarity

The sign of the gain is easily selected by choosing the polarity of the connections to the + and − inputs of the X G_M stage. Swapping between inverting and noninverting gain is possible simply by reversing the input connections. The response of the amplifier is identical in either connection, except for the sign change. The bandwidth, high impedance, transient behavior, etc., of the AD830, is symmetrical for both polarities of gain. This is very advantageous and unlike an op amp.

Input Impedance

The relatively high input impedance of the AD830, for a differential receiver amplifier, permits connections to modest impedance sources without much loading or loss of common-mode rejection. The nominal input resistance is 300 kΩ. The real limit to the upper value of the source resistance is in its effect on common-mode rejection and bandwidth. If the source resistance is in only one input, then the low frequency common-mode rejection will be lowered to $\approx R_{IN}/R_S$. The source resistance/input capacitance pole ($f = \frac{1}{2\pi} \times R_S \times C_{IN}$) limits the bandwidth. Furthermore, the high frequency common-mode rejection will be additionally lowered by the difference in the frequency response caused by the $R_S \times C_{IN}$ pole. Therefore, to maintain good low and high frequency common-mode rejection, it is recommended that the source resistances of the + and − inputs be matched and of modest value (≤10 kΩ).

Handling Bias Currents

The bias currents are typically 4 μA flowing into each pin of the G_M stages of the AD830. Since all applications possess some finite source resistance, the bias current through this resistor will create a voltage drop ($I_{BIAS} \times R_S$). The relatively high input impedance of the AD830 permits modest values of R_S, typically ≤10 kΩ. If the source resistance is in only one terminal, then an objectional offset voltage may result (e.g., 4 μA × 5 kΩ = 20 mV). Placement of an equal value resistor in series with the other input will cancel the offset to first order. However, due to mismatches in the resistances, a residual offset will remain and likely be greater than bias current (offset current) mismatches.

Applying Feedback

The AD830 is intended for use with gain from 1 to 100. Gains greater than one are simply set by a pair of resistors connected as shown in the difference amplifier (Figure 35) with gain >1. The value of the bottom resistor R_2, should be kept less than 1 kΩ to insure that the pole formed by C_{IN} and the parallel connection of R_1 and R_2 is sufficiently high in frequency so that it does not introduce excessive phase shift around the loop and destabilizes the amplifier. A compensating resistor, equal to the parallel combination of R_1 and R_2, should be placed in series with the other Y G_M stage input to preserve the high frequency common-mode rejection and to lower the offset voltage induced by the input bias current.

Output Common Mode

The output swing of the AD830 is defined by the differential input voltage, the gain and the output common. Depending on the anticipated signal span, the output common (or ground) may be set anywhere between the allowable peak output voltage in a manner similar to that described for input voltage common mode. A plot of the peak output voltage versus supply is shown in Figure 26. A prediction of the common-mode range versus the peak output differential voltage can be easily derived from the maximum output swing as $V_{OCM} = V_{MAX} - V_{PEAK}$.

Output Current

The absolute peak output current is set by the short circuit current limiting, typically greater that 60 mA. The maximum drive capability is rated at 50 mA, but without a guarantee of distortion performance. Best distortion performance is obtained by keeping the output current ≤20 mA. Attempting to drive large voltages into low valued resistances (e.g., 10 V into 150 Ω) will cause an apparent lowering of the limit for output signal swing, but is just the current limiting behavior.

Driving Cap Loads

The AD830 is capable of driving modest sized capacitive loads while maintaining its rated performance. Several curves of bandwidth versus capacitive load are given in Figures 15 and 18. The AD830 was designed primarily as a low distortion video speed amplifier, but with a tradeoff, giving up very large capacitive load driving capability. If very large capacitive loads must be driven, then the network shown in Figure 27 should be used to insure stable operation. If the loss of gain caused by the resistor R_S in series with the load is objectionable, then the optional feedback network shown may be added to restore the lost gain.

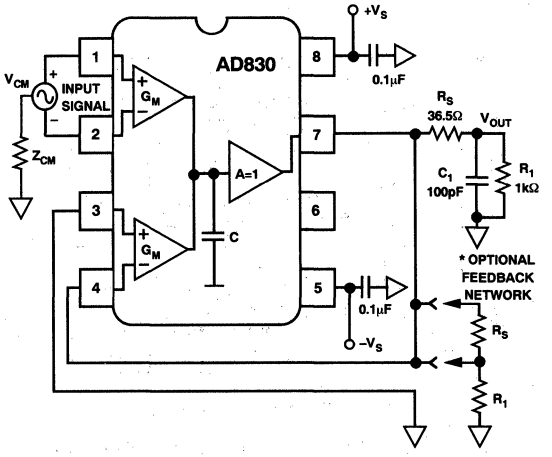

Figure 27. Circuit for Driving Large Capacitive Loads

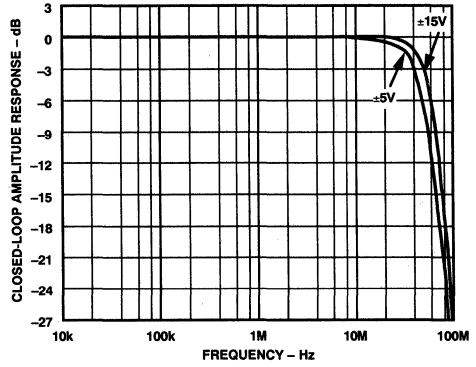

Figure 28. Closed-Loop Response vs. Frequency with 100 pF Load and Series Resistor Compensation

SUPPLIES, BYPASSING AND GROUNDING (Figure 29)
The AD830 is capable of operating over a wide range of supply voltages, both single and dual supplies. The coupling may be dc or ac provided the input and output voltages stay within the specified common-mode voltage limits. For dual supplies, the device works from ±4 V to ±16.5 V. Single supply operation is possible over +8 V to +33 V. It is also possible to operate the part with split supply voltages (e.g., +24 V, −5 V) for special applications such as level shifting. The primary constraint is that the total potential between the two supplies does not exceed 33 V.

Inclusion of power supply bypassing capacitors is necessary to achieve stable behavior and the specified performance. It is especially important when driving low resistance loads. At a minimum, connect a 0.1 μF ceramic capacitor at the supply lead of the AD830 package. In addition, for the best by passing, we recommend connecting a 0.01 μF ceramic capacitor and 4.7 μF tantalum capacitor to the supply lead going to the AD830.

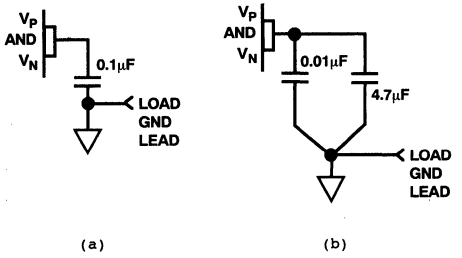

Figure 29. Supply Decoupling Options

The AD830 is designed by its functionality to be capable of rejecting noise and dissimilar potentials in the ground lines. Therefore, proper care is necessary to realize the benefits of the differential amplification of the part. Separation of the input and output grounds is crucial in rejection of the common mode noise at the inputs and eliminating any ground drops on the input signal line. For example, connecting the ground of a coaxial cable to the AD830 output common (board ground) could degrade the CMR and also introduce power-down loading on cable grounds. However, it is also necessary as in any electronic system, to provide a return path for bias currents back to their original power supply. This is accomplished by providing a connection between the differing grounds through a modest impedance labeled Z_{CM} (e.g., 100 Ω).

Single Supply Operation
The AD830 is capable of operating in single power supply applications down to a voltage of +8 V, with the generalized connection shown in Figure 30. There is a constraint on the common-mode voltage at the input and output which establishes the range for these voltages. Direct coupling may be used for input and output voltages which lie in these ranges. Any gain network applied needs to be referred to the output common connection or have an appropriate offset voltage. In situations where the signal lies at a common voltage outside the common mode range of the AD830 direct coupling will not work, so ac coupling should be used. A tested application included later in this data sheet (Figure 42), shows how to easily accomplish coupling to the AD830. For single supply operation where direct coupling is desired the input and output common-mode curves (Figures 31 and 32) should be used.

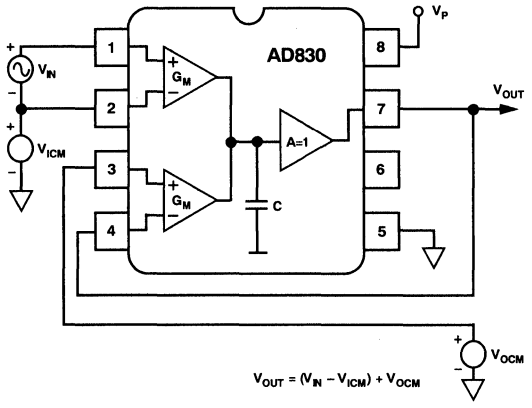

Figure 30. General Single Supply Connection

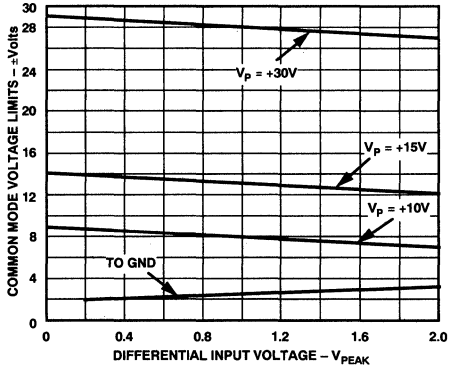

Figure 31. Input Common-Mode Range for Single Supply

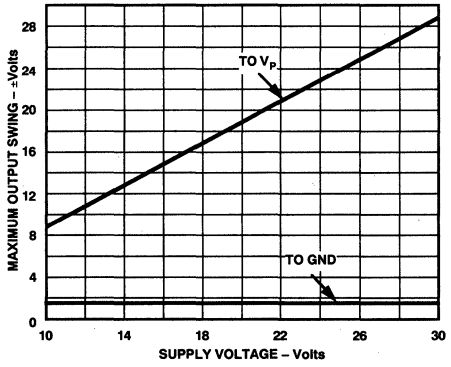

Figure 32. Output Swing Limit for Single Supply

Differential Line Receiver

The AD830 was specifically designed to perform as a differential line receiver. The circuit in Figure 33 shows how simple it is to configure the AD830 for this function. The signal from system "A" is received differentially relative to A's common, and that voltage is exactly reproduced relative to the common in system B. The common-mode rejection versus frequency, shown in Figure 1, is excellent, typically 100 dB at low frequencies. The high input impedance permits the AD830 to operate as a bridging amplifier across low impedance terminations with negligible loading. The differential gain and phase specifications are very good as shown in Figure 7 for 500 Ω and Figure 10 for 150 Ω. The input and output common should be separated to achieve the full CMR performance of the AD830 as a differential amplifier. However, a common return path is necessary between systems A and B.

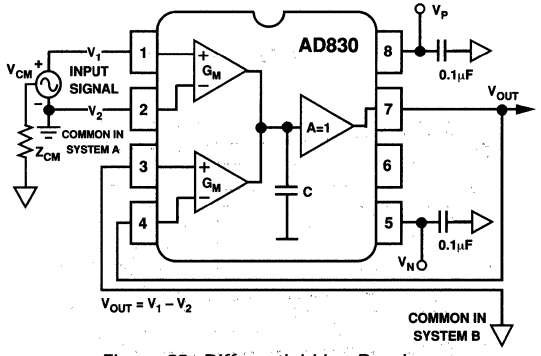

Figure 33. Differential Line Receiver

Wide Range Level Shifter

The wide common-mode range and accuracy of the AD830 allows easy level shifting of differential signals referred to an input common-mode voltage to any new voltage defined at the output. The inputs may be referenced to levels as high as 10 V at the inputs with a ±2 V swing about 10 V. In the circuit of Figure 34, the output voltage, V_{OUT}, is defined by the simple equation shown below. The excellent linearity and low distortion are preserved over the full input and output common-mode range. The voltage sources need not be of low impedance, since the high input resistance and modest input bias current of the AD830 V-to-I converters permit the use of resistive voltage dividers as reference voltages.

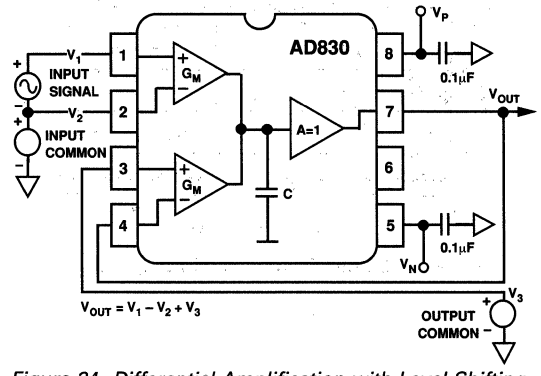

Figure 34. Differential Amplification with Level Shifting

Difference Amplifier with Gain > 1

The AD830 can provide instrumentation amplifier style differential amplification at gains greater than 1. The input signal is connected differentially and the gain is set via feedback resistors as shown in Figure 35. The gain, $G = (R_2 + R_1)/R_2$. The AD830 can provide either inverting or noninverting differential amplification. The polarity of the gain is established by the polarity of the connection at the input. Feedback resistors R_2 should generally be $R_2 \leq 1$ kΩ to maintain closed-loop stability and also keep bias current induced offsets low. Highest CMRR and lowest dc offsets are preserved by including a compensating resistor in series with Pin 3. The gain may be as high as 100.

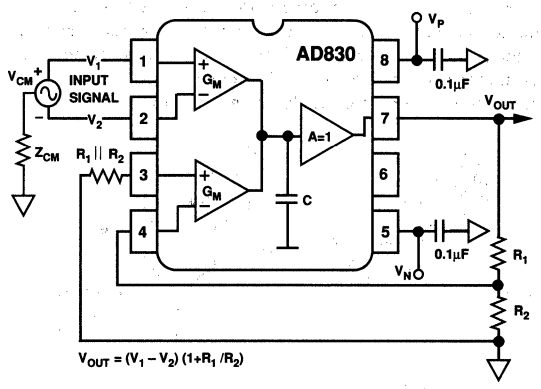

Figure 35. Gain of G Differential Amplifier, G > 1

Offsetting the Output with Gain

Some applications, such as A/D drivers, require that the signal be amplified and also offset, typically to accommodate the input range of the device. The AD830 can offset the output signal very simply through Pin 3 even with gain > 1. The voltage applied to Pin 3 must be attenuated by an appropriate factor so that $V_3 \times G$ = desired offset. In Figure 36, a resistive divider from a voltage reference is used to produce the attenuated offset voltage.

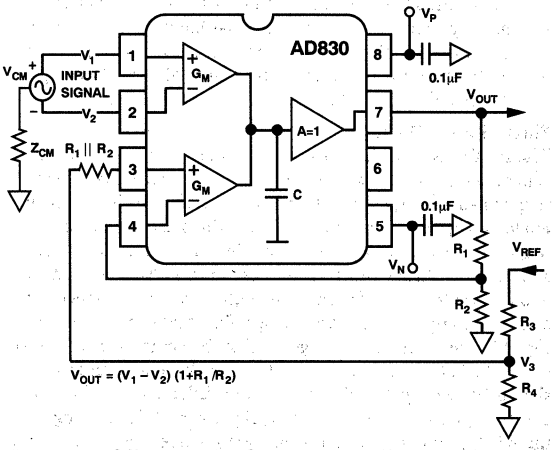

Figure 36. Offsetting the Output with Differential Gain > 1

Loop Through or Line Bridging Amplifier (Figure 37)
The AD830 is ideally suited for use as a video line bridging amplifier. The video signal is tapped from the conductor of the cable relative to its shield. The high input impedance of the AD830 provides negligible loading on the cable. More significantly, the benign loading is maintained while the AD830 is powered-down. Coupled with its good video load driving performance, the AD830 is well suited to video cable monitoring applications.

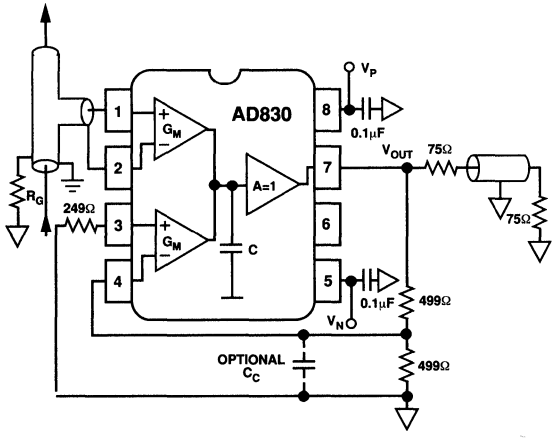

Figure 37. Cable Tap Amplifier

Resistorless Summing
Direct, two input, resistorless summing is easily realized from the general unity gain mode. By grounding V_{X2} and applying the two inputs to V_{X1} and V_{Y1}, the output is the exact sum of the applied voltages V_1 and V_3, relative to common; $V_{OUT} = V_1 + V_3$. A diagram of this simple, but potent application is shown below in Figure 38. The AD830 summing circuit possesses several virtues not present in the classic op amp based summing circuits. It has high impedance inputs, no resistors, very precise summing, high reverse isolation and noninverting gain. Achieving this function and performance with op amps requires significantly more components.

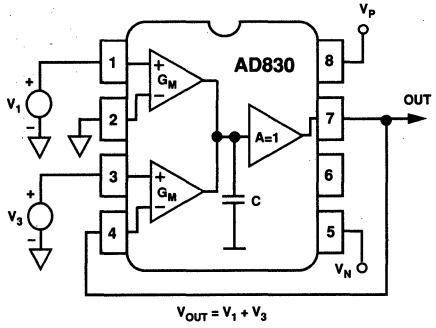

Figure 38. Resistorless Summing Amplifier

2× Gain Bandwidth Line Driver
A gain of two, without the use of resistors, is possible with the AD830. This is accomplished by grounding V_{X2}, tying the two inputs V_{X1} and V_{Y1} together and applying the input, V_{IN}, to this wired connection. The output is exactly twice the applied voltage, V_{IN}; $V_{OUT} = 2 \times V_{IN}$. Figure 39 below shows the connections for this highly useful application. The most notable characteristic of this alternative gain of two is that there is no loss of bandwidth as in a voltage feedback op amp based gain of +2 where the bandwidth is halved, therefore, the gain bandwidth is doubled. Also, this circuit is accurate without the need for any precise valued resistors, as in the op amp equivalents, and it possess excellent differential gain and phase performance as shown in Figures 40 and 41.

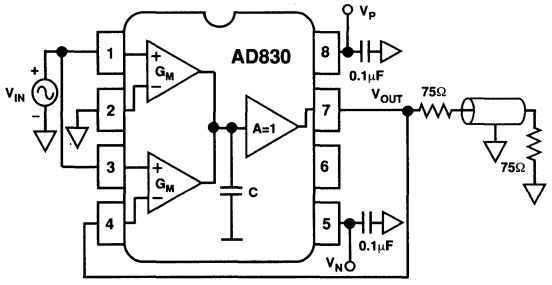

Figure 39. Full Bandwidth Line Driver (G = +2)

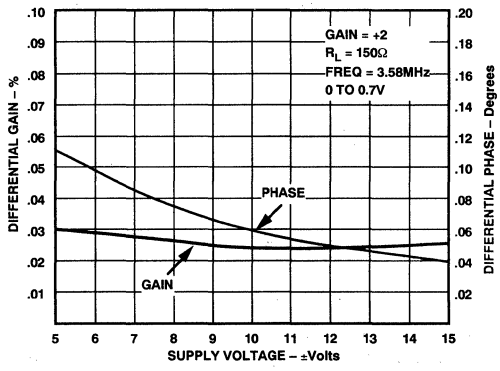

Figure 40. Differential Gain and Phase for the Circuit of Figure 39

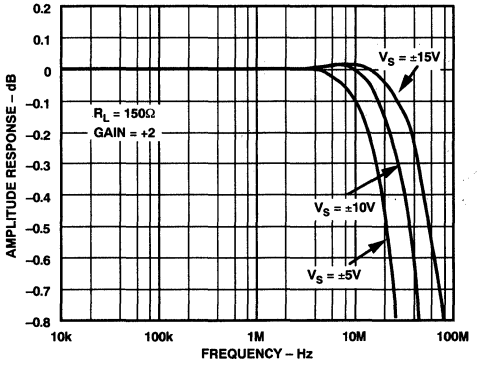

Figure 41. 0.1 dB Gain Flatness for the Circuit of Figure 39

AC COUPLED LINE RECEIVER

The AD830 is configurable as an ac coupled differential amplifier on a single or bipolar supply voltages. All that is needed is inclusion of a few noncritical passive components as illustrated below in Figure 42. A simple resistive network at the X G_M input establishes a common-mode bias. Here, the common mode is centered at 6 volts, but in principle can be any voltage within the common-mode limits of the AD830. The 10 kΩ resistors to each input bias the X G_M stage with sufficiently high impedance to keep the input coupling corner frequency low, but not too large so that residual bias current induced offset voltage becomes troublesome. For dual supply operation, the 10 kΩ resistors may go directly to ground. The output common is conveniently set by a Zener diode for a low impedance reference to preserve the high frequency CMR. However, a simple resistive divider will work fine and good high frequency CMR can be maintained by placing a compensating resistor in series with the +Y input. The excellent CMRR response of the circuit is shown in Figure 43. A plot of the 0.1 dB flatness from 10 Hz is also shown. With the use of 10 μF capacitors, the CMR is >90 dB down to a few tens of hertz. This level of performance is almost impossible to achieve with discrete solutions.

ANALOG DEVICES

Wideband, Fast Settling Op Amp

AD840

FEATURES

Wideband AC Performance
- Gain Bandwidth Product: 400 MHz (Gain ≥ 10)
- Fast Settling: 100 ns to 0.01% for a 10 V Step
- Slew Rate: 400 V/μs
- Stable at Gains of 10 or Greater
- Full Power Bandwidth: 6.4 MHz for 20 V p–p into a 500 Ω Load

Precision DC Performance
- Input Offset Voltage: 0.3 mV max
- Input Offset Drift: 3 μV/°C typ
- Input Voltage Noise: 4 nV/$\sqrt{Hz}$
- Open-Loop Gain: 130 V/mV into a 1 kΩ Load
- Output Current: 50 mA min
- Supply Current: 12 mA max

APPLICATIONS

- Video and Pulse Amplifiers
- DAC and ADC Buffers
- Line Drivers
- Available in 14-Pin Plastic DIP, Hermetic Cerdip and 20-Pin LCC Packages and in Chip Form
- MIL-STD-883B Processing Available

PRODUCT DESCRIPTION

The AD840 is a member of the Analog Devices' family of wide bandwidth operational amplifiers. This high speed/high precision family includes, among others, the AD841, which is unity-gain stable, and the AD842, which is stable at a gain of two or greater and has 100 mA minimum output current drive. These devices are fabricated using Analog Devices' junction isolated complementary bipolar (CB) process. This process permits a combination of dc precision and wideband ac performance previously unobtainable in a monolithic op amp. In addition to its 400 MHz gain bandwidth product, the AD840 offers extremely fast settling characteristics, typically settling to within 0.01% of final value in 100 ns for a 10 volt step.

The AD840 remains stable over its full operating temperature range at closed-loop gains of 10 or greater. It also offers a low quiescent current of 12 mA maximum, a minimum output current drive capability of 50 mA, a low input voltage noise of 4 nV/$\sqrt{Hz}$ and a low input offset voltage of 0.3 mV maximum (AD840K).

The 400 V/μs slew rate of the AD840, along with its 400 MHz gain bandwidth, ensures excellent performance in video and pulse amplifier applications. This amplifier is ideally suited for use in high frequency signal conditioning circuits and wide bandwidth active filters. The extremely rapid settling time of the AD840 makes it the preferred choice for data acquisition applications which require 12-bit accuracy. The AD840 is also appropriate for other applications such as high speed DAC and ADC buffer amplifiers and other wide bandwidth circuitry.

APPLICATION HIGHLIGHTS

1. The high slew rate and fast settling time of the AD840 make it ideal for DAC and ADC buffers, line drivers and all types of video instrumentation circuitry.
2. The AD840 is truly a precision amplifier. It offers 12-bit accuracy to 0.01% or better and wide bandwidth, performance previously available only in hybrids.
3. The AD840's thermally balanced layout and the high speed of the CB process allow the AD840 to settle to 0.01% in 100 ns without the long "tails" that occur with other fast op amps.
4. Laser wafer trimming reduces the input offset voltage to 0.3 mV max on the K grade, thus eliminating the need for external offset nulling in many applications. Offset null pins are provided for additional versatility.
5. Full differential inputs provide outstanding performance in all standard high frequency op amp applications where circuit gain will be 10 or greater.
6. The AD840 is an enhanced replacement for the HA2540.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

Wideband, Unity-Gain Stable, Fast Settling Op Amp

AD841

FEATURES

AC PERFORMANCE
Unity-Gain Bandwidth: 40 MHz
Fast Settling: 110 ns to 0.01%
Slew Rate: 300 V/μs
Full Power Bandwidth: 4.7 MHz for 20 V p–p into a 500 Ω Load

DC PERFORMANCE
Input Offset Voltage: 1 mV max
Input Voltage Noise: 13 nV/$\sqrt{Hz}$ typ
Open-Loop Gain: 45 V/mV into a 1 kΩ Load
Output Current: 50 mA min
Supply Current: 12 mA max

APPLICATIONS
High Speed Signal Conditioning
Video and Pulse Amplifiers
Data Acquisition Systems
Line Drivers
Active Filters
Available in 14-Pin Plastic DIP, Hermetic Cerdip, 12-Pin TO-8 Metal Can and 20-Pin LCC Packages
Chips and MIL-STD-883B Parts Available

PRODUCT DESCRIPTION

The AD841 is a member of the Analog Devices family of wide bandwidth operational amplifiers. This high speed/high precision family includes, among others, the AD840, which is stable at a gain of 10 or greater, and the AD842, which is stable at a gain of two or greater and has 100 mA minimum output current drive. These devices are fabricated using Analog Devices' junction isolated complementary bipolar (CB) process. This process permits a combination of dc precision and wideband ac performance previously unobtainable in a monolithic op amp. In addition to its 40 MHz unity-gain bandwidth product, the AD841 offers extremely fast settling characteristics, typically settling to within 0.01% of final value in 110 ns for a 10 volt step.

Unlike many high frequency amplifiers, the AD841 requires no external compensation. It remains stable over its full operating temperature range. It also offers a low quiescent current of 12 mA maximum, a minimum output current drive capability of 50 mA, a low input voltage noise of 13 nV/$\sqrt{Hz}$ and low input offset voltage of 1 mV maximum.

The 300 V/μs slew rate of the AD841, along with its 40 MHz gain bandwidth, ensures excellent performance in video and pulse amplifier applications. This amplifier is well suited for use in high frequency signal conditioning circuits and wide bandwidth active filters. The extremely rapid settling time of the AD841 makes it the preferred choice for data acquisition applications which require 12-bit accuracy. The AD841 is also appropriate for other applications such as high speed DAC and ADC buffer amplifiers and other wide bandwidth circuitry.

PRODUCT DESCRIPTION

The AD842 is a member of the Analog Devices family of wide bandwidth operational amplifiers. This family includes, among others, the AD840 which is stable at a gain of 10 or greater and the AD841 which is unity-gain stable. These devices are fabricated using Analog Devices' junction isolated complementary bipolar (CB) process. This process permits a combination of dc precision and wideband ac performance previously unobtainable in a monolithic op amp. In addition to its 80 MHz gain bandwidth, the AD842 offers extremely fast settling characteristics, typically settling to within 0.01% of final value in less than 100 ns for a 10 volt step.

The AD842 also offers a low quiescent current of 13 mA, a high output current drive capability (100 mA minimum), a low input voltage noise of 9 nV/$\sqrt{Hz}$ and a low input offset voltage (1 mV maximum).

The 375 V/μs slew rate of the AD842, along with its 80 MHz gain bandwidth, ensures excellent performance in video and pulse amplifier applications. This amplifier is ideally suited for use in high frequency signal conditioning circuits and wide bandwidth active filters. The extremely rapid settling time of the AD842 makes this amplifier the preferred choice for data acquisition applications which require 12-bit accuracy. The AD842 is also appropriate for other applications such as high speed DAC and ADC buffer amplifiers and other wide bandwidth circuitry.

APPLICATION HIGHLIGHTS

1. The high slew rate and fast settling time of the AD842 make it ideal for DAC and ADC buffers amplifiers, lines drivers and all types of video instrumentation circuitry.
2. The AD842 is a precision amplifier. It offers accuracy to 0.01% or better and wide bandwidth; performance previously available only in hybrids.
3. Laser-wafer trimming reduces the input offset voltage of 1 mV max, thus eliminating the need for external offset nulling in many applications.
4. Full differential inputs provide outstanding performance in all standard high frequency op amp applications where the circuit gain will be 2 or greater.
5. The AD842 is an enhanced replacement for the HA2542.

34 MHz, CBFET Fast Settling Op Amp

AD843

FEATURES

AC PERFORMANCE
- Unity Gain Bandwidth: 34 MHz
- Fast Settling: 135 ns to 0.01%
- Slew Rate: 250 V/μs
- Stable at Gains of 1 or Greater
- Full Power Bandwidth: 3.9 MHz

DC PERFORMANCE
- Input Offset Voltage: 1 mV max (AD843K/B)
- Input Bias Current: 0.6 nA typ
- Input Voltage Noise: 19 nV/$\sqrt{Hz}$
- Open Loop Gain: 30 V/mV into a 500 Ω Load
- Output Current: 50 mA min
- Supply Current: 13 mA max
- Available in 8-Pin Plastic Mini-DIP & Cerdip, 16-Pin SOIC, 20-Pin LCC and 12-Pin Hermetic Metal Can Packages
- Available in Tape and Reel in Accordance with EIA-481A Standard
- Chips and MIL-STD-883B Parts Also Available

APPLICATIONS
- High Speed Sample-and-Hold Amplifiers
- High Bandwidth Active Filters
- High Speed Integrators
- High Frequency Signal Conditioning

PRODUCT DESCRIPTION

The AD843 is a fast settling, 34 MHz, CBFET input op amp. The AD843 combines the low (0.6 nA) input bias currents characteristic of a FET input amplifier while still providing a 34 MHz bandwidth and a 135 ns settling time (to within 0.01% of final value for a 10 volt step). The AD843 is a member of the Analog Devices' family of wide bandwidth operational amplifiers. These devices are fabricated using Analog Devices' junction isolated complementary bipolar (CB) process. This process permits a combination of dc precision and wideband ac performance previously unobtainable in a monolithic op amp.

The 250 V/μs slew rate and 0.6 nA input bias current of the AD843 ensure excellent performance in high speed sample-and-hold applications and in high speed integrators. This amplifier is also ideally suited for high bandwidth active filters and high frequency signal conditioning circuits.

Unlike many high frequency amplifiers, the AD843 requires no external compensation and it remains stable over its full operating temperature range. It is available in five performance grades: the AD843J and AD843K are rated over the commercial temperature range of 0°C to +70°C. The AD843A and AD843B are rated over the industrial temperature range of −40°C to +85°C. The AD843S is rated over the military temperature range of −55°C to +125°C and is available processed to MIL-STD-883B, Rev. C.

The AD843 is offered in either 8-pin plastic DIP or hermetic cerdip packages, in 16-pin SOIC, 20-Pin LCC, or in a 12-pin metal can. Chips are also available.

PRODUCT HIGHLIGHTS

1. The high slew rate, fast settling time and low input bias current of the AD843 make it the ideal amplifier for 12-bit D/A and A/D buffers, for high speed sample-and-hold amplifiers and for high speed integrator circuits. The AD843 can replace many FET input hybrid amplifiers such as the LH0032, LH4104 and OPA600.
2. Fully differential inputs provide outstanding performance in all standard high frequency op amp applications such as signal conditioning and active filters.
3. Laser wafer trimming reduces the input offset voltage to 1 mV max (AD843K and AD843B).
4. Although external offset nulling is unnecessary in many applications, offset null pins are provided.
5. The AD843 does not require external compensation at closed loop gains of 1 or greater.

ANALOG DEVICES

60 MHz, 2000 V/μs Monolithic Op Amp

AD844

FEATURES

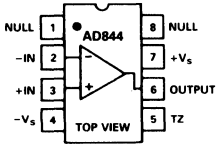
Wide Bandwidth: 60MHz at Gain of −1
33MHz at Gain of −10
Very High Output Slew Rate: Up to 2000V/μs
20MHz Full Power Bandwidth, 20V pk-pk, R_L=500Ω
Fast Settling: 100ns to 0.1% (10V Step)
Differential Gain Error: 0.03% at 4.4MHz
Differential Phase Error: 0.15° at 4.4MHz
High Output Drive: ±50mA into 50Ω Load
Low Offset Voltage: 150μV max (B Grade)
Low Quiescent Current: 6.5mA
Available in Tape and Reel in Accordance with EIA-481A Standard

APPLICATIONS

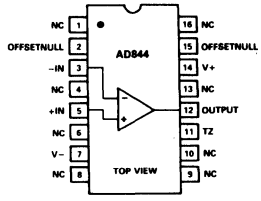
Flash ADC Input Amplifiers
High Speed Current DAC Interfaces
Video Buffers and Cable Drivers
Pulse Amplifiers

CONNECTION DIAGRAMS

8-Pin Plastic (N), and Cerdip (Q) Packages



16-Pin SOIC (R) Package



PRODUCT DESCRIPTION

The AD844 is a high speed monolithic operational amplifier fabricated using Analog Devices' junction isolated complementary bipolar (CB) process. It combines high bandwidth and very fast large signal response with excellent dc performance. Although optimized for use in current to voltage applications and as an inverting mode amplifier, it is also suitable for use in many non-inverting applications.

The AD844 can be used in place of traditional op amps, but its current feedback architecture results in much better ac performance, high linearity and an exceptionally clean pulse response.

This type of op amp provides a closed-loop bandwidth which is determined primarily by the feedback resistor and is almost independent of the closed-loop gain. The AD844 is free from the slew rate limitations inherent in traditional op amps and other current-feedback op amps. Peak output rate of change can be over 2000V/μs for a full 20V output step. Settling time is typically 100ns to 0.1%, and essentially independent of gain. The AD844 can drive 50Ω loads to ±2.5V with low distortion and is short circuit protected to 80mA.

The AD844 is available in four performance grades and three package options. In the 16-pin SOIC (R) package, the AD844J is specified for the commercial temperature range of 0 to +70°C. The AD844A and AD844B are specified for the industrial temperature range of −40°C to +85°C and are available in the cerdip (Q) package. The AD844A is also available in an 8-pin plastic mini-DIP (N). The AD844S is specified over the military temperature range of −55°C to +125°C. It is available in the 8-pin cerdip (Q) package. "A" and "S" grade chips and devices processed to MIL-STD-883B, REV. C are also available.

PRODUCT HIGHLIGHTS

1. The AD844 is a versatile, low cost component providing an excellent combination of ac and dc performance. It may be used as an alternative to the EL2020 and CLC400/1.
2. It is essentially free from slew rate limitations. Rise and fall times are essentially independent of output level.
3. The AD844 can be operated from ±4.5V to ±18V power supplies and is capable of driving loads down to 50Ω, as well as driving very large capacitive loads using an external network.
4. The offset voltage and input bias currents of the AD844 are laser trimmed to minimize dc errors; V_{OS} drift is typically 1μV/°C and bias current drift is typically 9nA/°C.
5. The AD844 exhibits excellent differential gain and differential phase characteristics, making it suitable for a variety of video applications with bandwidths up to 60MHz.
6. The AD844 combines low distortion, low noise and low drift with wide bandwidth, making it outstanding as an input amplifier for flash A/D converters.

SUBTRATE CONNECTED TO +V_S

Precision, 16 MHz CBFET Op Amp

AD845

FEATURES

Replaces Hybrid Amplifiers in Many Applications

AC PERFORMANCE:

Settles to 0.01% in 350 ns
100 V/μs Slew Rate
12.8 MHz min Unity-Gain Bandwidth
1.75 MHz Full-Power Bandwidth at 20 V p–p

DC PERFORMANCE:

0.25 mV max Input Offset Voltage
5 μV/°C max Offset Voltage Drift
0.5 nA Input Bias Current
250 V/mV min Open-Loop Gain
4 μV p–p max Voltage Noise, 0.1 Hz to 10 Hz
94 dB min CMRR
Available in Plastic Mini-DIP, Hermetic Cerdip and SOIC Packages. Also Available in Tape and Reel in Accordance with EIA-481A Standard

PRODUCT DESCRIPTION

The AD845 is a fast, precise, N channel JFET input, monolithic operational amplifier. It is fabricated using Analog Devices' complementary bipolar (CB) process. Advanced laser-wafer trimming technology enables the very low input offset voltage and offset voltage drift performance to be realized. This precision, when coupled with a slew rate of 100 V/μs, a stable unity-gain bandwidth of 16 MHz, and a settling time of 350 ns 0.01%—while driving a parallel load of 100 pF and 500 Ω—represents a combination of features unmatched by any FET input IC amplifier. The AD845 can easily be used to upgrade many existing designs which use BiFET or FET input hybrid amplifiers and, in some cases, those which use bipolar input op amps.

The AD845 is ideal for use in applications such as active filters, high speed integrators, photo diode preamps, sample-and-hold amplifiers, log amplifiers, and in buffering A/D and D/A converters. The 250 μV max input offset voltage makes offset nulling unnecessary in many applications. The common-mode rejection ratio of 110 dB over a ±10 V input voltage range represents exceptional performance for a JFET input high speed op amp. This, together with a minimum open-loop gain of 250 V/mV ensures that 12-bit performance is achieved, even in unity-gain buffer circuits.

The AD845 conforms to the standard op amp pinout except that offset nulling is to V+. The AD845J and AD845K grade devices are available specified to operate over the commercial 0 to +70°C temperature range. AD845A and AD845B devices are specified for operation over the −40°C to +85°C industrial temperature range. The AD845S is specified to operate over the full military temperature range of −55°C to +125°C. Both the industrial and military versions are available in 8-pin cerdip packages. The commercial version is available in an 8-pin plastic mini-DIP and 16-pin SOIC; "J" and "S" grade chips are also available.

PRODUCT HIGHLIGHTS

1. The high slew rate, fast settling time, and dc precision of the AD845 make it ideal for high speed applications requiring 12-bit accuracy.
2. The performance of circuits using the LF400, HA2520/2/5, HA2620/2/5, 3550, OPA605, and LH0062 can be upgraded in most cases.
3. The AD845 is unity-gain stable and internally compensated.
4. The AD845 is specified while driving 100 pF/500 Ω loads.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

450 V/μs, Precision, Current-Feedback Op Amp

AD846

FEATURES

AC PERFORMANCE
Small Signal Bandwidth: 80 MHz (A_V = −1)
Slew Rate: 450 V/μs
Full Power Bandwidth: 6.8 MHz at 20 V p-p, R_L = 500 Ω
Fast Settling: for 10 V Step: 110 ns to 0.01%, 80 ns to 0.1%
Differential Gain: <0.01% @ 4.4 MHz
Differential Phase: <0.028° @ 4.4 MHz
Total Harmonic Distortion (THD): 0.0005% @ 100 kHz
Open-Loop Transimpedance: 200 MΩ
Input Voltage Noise: 2 nV/√Hz

DC PERFORMANCE
Input Offset Voltage: 75 μV max (B Grade)
Input Offset Drift: 3.5 μV/°C max (B Grade)
Quiescent Supply Current: 6.5 mA max

APPLICATIONS
High Speed DAC Buffers
Multiflash ADC Error Amplifiers
Flash ADC Buffers
Coaxial Cable Drivers
High Performance Audio Circuitry
Available in Plastic Mini-DIP, Hermetic Cerdip, and Hermetic Metal Can Packages
MIL-STD-883B Parts Available

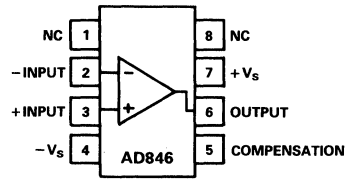
PRODUCT DESCRIPTION

The AD846 is a monolithic, very high speed operational amplifier offering high performance. Although technically classed as a current-feedback or transimpedance amplifier, it may be used in much the same way as traditional op amps while providing significant performance benefits. Employing Analog Devices' junction isolated complementary bipolar (CB) process, the AD846 achieves true "12-bit" (0.01%) precision on critical ac and dc parameters, a level of performance unmatched by amplifiers fabricated using either the dielectrically isolated (DI) or other bipolar processes.

The AD846 offers significant advantages over conventional high speed operational amplifiers. It maintains a nearly constant bandwidth and settling time to 0.01% over a wide range of closed-loop gains. This makes the AD846 ideal for amplifying the residue in multiple-pass analog-to-digital converters.

CONNECTION DIAGRAM

Plastic Mini-DIP (N) Package and Cerdip (Q) Package



NC = NO CONNECT
TOP VIEW

Other advantages include: low input errors and high open-loop transresistance (200 MΩ) into a 500 Ω load, ensuring true 12-bit dc accuracy for closed-loop gains from −1 to gains greater than −100. This combination of ac and dc performance makes the AD846 an excellent choice for buffering precision high speed DACs and flash ADCs.

The AD846 is available in three performance grades. The AD846A and AD846B are rated over the industrial temperature range of −40°C to +85°C. The AD846S is rated over the full military temperature range of −55°C to +125°C and is available processed to MIL-STD-883B, Rev C.

Extended reliability PLUS screening is available specified over the commercial temperature range. PLUS screening includes 168 hour burn-in as well as other environmental and physical tests. The AD846 is available in two types of 8-pin package: plastic mini-DIP and hermetic cerdip. "A" and "S" grade chips are also available.

PRODUCT HIGHLIGHTS

1. The AD846 achieves settling times of 110 ns to 0.01% for gains of −1 to −10, with a 450 V/μs slew rate, while consuming only 5 mA of supply current.
2. For closed-loop gains of −1 to −100, the high speed performance of the AD846 is achieved without sacrificing full 12-bit dc precision.
3. The AD846 is well suited to line driver and video buffer applications where the properties of low distortion and high slew rate are required.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

High Speed, Low Power Monolithic Op Amp

AD847

FEATURES

Superior Performance
- High Unity Gain BW: 50 MHz
- Low Supply Current: 5.3 mA
- High Slew Rate: 300 V/μs
- Excellent Video Specifications
  - 0.04% Differential Gain (NTSC and PAL)
  - 0.19° Differential Phase (NTSC and PAL)
- Drives Any Capacitive Load
- Fast Settling Time to 0.1% (10 V Step): 65 ns
- Excellent DC Performance
  - High Open-Loop Gain 5.5 V/mV (R_{LOAD} = 1 kΩ)
  - Low Input Offset Voltage: 0.5 mV
- Specified for ±5 V and ±15 V Operation
- Available in a Wide Variety of Options
  - Plastic DIP and SOIC Packages
  - Cerdip Package
  - Die Form
  - MIL-STD-883B Processing
  - Tape & Reel (EIA-481A Standard)
- Dual Version Available: AD827 (8 Lead)
- Enhanced Replacement for LM6361
- Replacement for HA2544, HA2520/2/5 and EL2020

APPLICATIONS

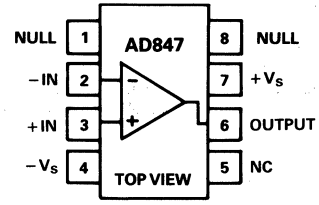
- Video Instrumentation
- Imaging Equipment
- Copiers, Fax, Scanners, Cameras
- High Speed Cable Driver
- High Speed DAC and Flash ADC Buffers

PRODUCT DESCRIPTION

The AD847 represents a breakthrough in high speed amplifiers offering superior ac & dc performance and low power, all at low cost. The excellent dc performance is demonstrated by its ±5 V specifications which include an open-loop gain of 3500 V/V (500 Ω load) and low input offset voltage of 0.5 mV. Common-mode rejection is a minimum of 78 dB. Output voltage swing is ±3 V into loads as low as 150 Ω. Analog Devices also offers over 30 other high speed amplifiers from the low noise AD829 (1.7 nV/$\sqrt{Hz}$) to the ultimate video amplifier, the AD811, which features 0.01% differential gain and 0.01° differential phase.

CONNECTION DIAGRAM

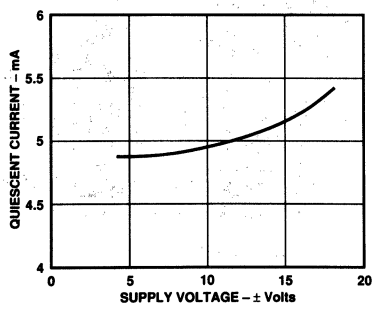
Plastic DIP (N), Small Outline (R) and Cerdip (Q) Packages



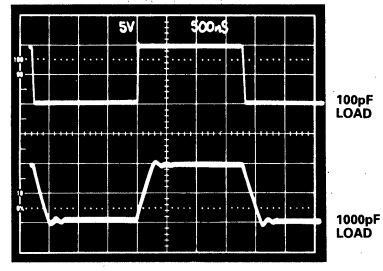
NC = NO CONNECT

APPLICATION HIGHLIGHTS

1. As a buffer the AD847 offers a full-power bandwidth of 12.7 MHz (5 V p–p with ±5 V supplies) making it outstanding as an input buffer for flash A/D converters.
2. The low power and small outline package of the AD847 make it very well suited for high density applications such as multiple pole active filters.
3. The AD847 is internally compensated for unity gain operation and remains stable when driving any capacitive load.



Quiescent Current vs. Supply Voltage



AD847 Driving Capacitive Loads

Junction Temperature . . . . . 175°C
Lead Temperature Range (Soldering 60 sec) . . . . . 300°C

NOTES
[1]Stresses above those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. This is a stress rating only, and functional operation of the device at these or any other conditions above those indicated in the operational section of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.
[2]Mini-DIP Package: θ_{JA} = 100°C/Watt; θ_{JC} = 33°C/Watt
Cerdip Package: θ_{JA} = 110°C/Watt; θ_{JC} = 30°C/Watt
Small Outline Package: θ_{JA} = 155°C/Watt; θ_{JC} = 33°C/Watt

ESD SUSCEPTIBILITY

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 volts, which readily accumulate on the human body and on test equipment, can discharge without detection. Although the AD847 features proprietary ESD protection circuitry, permanent damage may still occur on these devices if they are subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid any performance degradation or loss of functionality.

High Speed, Low Power Monolithic Op Amps

AD848/AD849

FEATURES

725MHz Gain Bandwidth – AD849
175MHz Gain Bandwidth – AD848
4.8mA Supply Current
300V/μs Slew Rate
80ns Settling Time to 0.1% for a 10V Step – AD849
Differential Gain: AD848 = 0.07%, AD849 = 0.08%
Differential Phase: AD848 = 0.08°, AD849 = 0.04°
Drives Capacitive Loads

DC PERFORMANCE

3nV/√Hz Input Voltage Noise – AD849
85V/mV Open Loop Gain into a 1kΩ Load – AD849
1mV max Input Offset Voltage
Performance Specified for ±5V and ±15V Operation
Available in Plastic, Hermetic Cerdip and Small Outline Packages. Chips and MIL-STD-883B Parts Available.
Available in Tape and Reel in Accordance with EIA-481A Standard

APPLICATIONS

Cable Drivers
8- and 10-Bit Data Acquisition Systems
Video and R_F Amplification
Signal Generators

PRODUCT DESCRIPTION

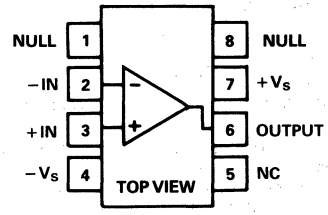
The AD848 and AD849 are high speed, low power monolithic operational amplifiers. The AD848 is internally compensated so that it is stable for closed loop gains of 5 or greater. The AD849 is fully decompensated and is stable at gains greater than 24. The AD848 and AD849 achieve their combination of fast ac and good dc performance by utilizing Analog Devices' junction isolated complementary bipolar (CB) process. This process enables these op amps to achieve their high speed while only requiring 4.8mA of current from the power supplies.

The AD848 and AD849 are members of Analog Devices' family of high speed op amps. This family includes, among others, the AD847 which is unity gain stable, with a gain bandwidth of 50MHz. For more demanding applications, the AD840, AD841 and AD842 offer even greater precision and greater output current drive.

The AD848 and AD849 have good dc performance. When operating with ±5V supplies, they offer open loop gains of 13V/mV (AD848 with a 500Ω load) and low input offset voltage of 1mV maximum. Common-mode rejection is a minimum of 92dB. Output voltage swing is ±3V even into loads as low as 150Ω.

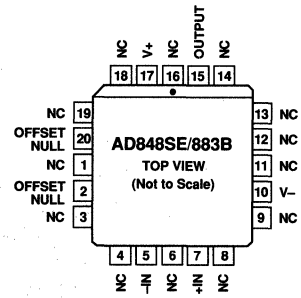
CONNECTION DIAGRAMS

Plastic (N), Small Outline (R) and Cerdip (Q) Packages



NC = NO CONNECT

20-Terminal LCC Pinout



APPLICATIONS HIGHLIGHTS

1. The high slew rate and fast settling time of the AD848 and AD849 make them ideal for video instrumentation circuitry, low noise pre-amps and line drivers.
2. In order to meet the needs of both video and data acquisition applications, the AD848 and AD849 are optimized and tested for ±5V and ±15V power supply operation.
3. Both amplifiers offer full power bandwidth greater than 20MHz (for 2V p-p with ±5V supplies).
4. The AD848 and AD849 remain stable when driving any capacitive load.
5. Laser wafer trimming reduces the input offset voltage to 1mV maximum on all grades, thus eliminating the need for external offset nulling in many applications.
6. The AD848 is an enhanced replacement for the LM6164 series and can function as a pin-for-pin replacement for many high speed amplifiers such as the HA2520/2/5 and EL2020 in applications where the gain is 5 or greater.

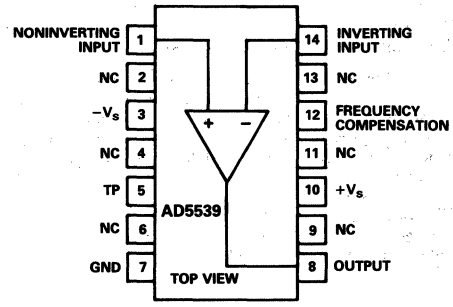
or Cerdip (Q) Package



PRODUCT DESCRIPTION

The AD5539 is an ultrahigh frequency operational amplifier designed specifically for use in video circuits and RF amplifiers. Requiring no external compensation for gains greater than 5, it may be operated at lower gains with the addition of external compensation.

As a superior replacement for the Signetics NE/SE5539, each AD5539 is 100% dc tested to meet all of its guaranteed dc specifications over the full temperature range of the device.

The high slew rate and wide bandwidth of the AD5539 provide low cost solutions to many otherwise complex and expensive high frequency circuit design problems.

The AD5539 is available specified to operate over either the commercial (AD5539JN/JQ) or military (AD5539SQ) temperature range. The commercial grade is available either in 14-pin plastic or cerdip packages. The military version is supplied in the cerdip package. Chip versions are also available.

PRODUCT HIGHLIGHTS

1. All guaranteed dc specifications are 100% tested.
2. The AD5539 drives 50 Ω and 75 Ω loads directly.
3. Input voltage noise is less than 4 $nV\sqrt{Hz}$.
4. Low cost RF and video speed performance.
5. ±2 volt output range into a 150 Ω load.
6. Low cost.
7. Chips available.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

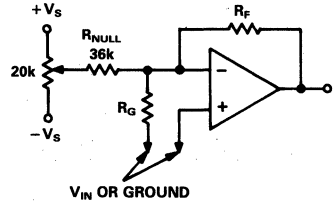
NOTE
[1]Stresses above those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. This is a stress rating only and functional operation of the device at these or any other conditions above those indicated in the operational section of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.

OFFSET NULL CONFIGURATION



OUTPUT NULL RANGE ≅ $+V_S\left(\frac{R_F}{R_{NULL}}\right)$ TO $-V_S\left(\frac{R_F}{R_{NULL}}\right)$

OFFSET NULL CONFIGURATION

800 MHz, 50 mW Current Feedback Amplifier

AD8001

FEATURES

Excellent Video Specifications (R_L = 150 Ω, G = +2)
- **Gain Flatness 0.1 dB to 100 MHz**
- **0.01% Differential Gain Error**
- **0.025° Differential Phase Error**

Low Power
- **5.5 mA max Power Supply Current (55 mW)**

High Speed and Fast Settling
- **880 MHz, –3 dB Bandwidth (G = +1)**
- **440 MHz, –3 dB Bandwidth (G = +2)**
- **1200 V/μs Slew Rate**
- **10 ns Settling Time to 0.1%**

Low Distortion
- **–65 dBc THD, f_C = 5 MHz**
- **33 dBm 3rd Order Intercept, F_1 = 10 MHz**
- **–66 dB SFDR, f = 5 MHz**

High Output Drive
- **70 mA Output Current**
- **Drives Up to 4 Back-Terminated Loads (75 Ω Each) While Maintaining Good Differential Gain/Phase Performance (0.05%/0.25°)**

APPLICATIONS

A-to-D Driver
Video Line Driver
Professional Cameras
Video Switchers
Special Effects
RF Receivers

PRODUCT DESCRIPTION

The AD8001 is a low power, high speed amplifier designed to operate on ±5 V supplies. The AD8001 features unique transimpedance linearization circuitry. This allows it to drive video loads with excellent differential gain and phase performance on only 50 mW of power. The AD8001 is a current feedback amplifier and features gain flatness of 0.1 dB to 100 MHz while offering differential gain and phase error of 0.01% and 0.025°. This makes the AD8001 ideal for professional video electronics such as cameras and video switchers. Additionally, the AD8001's low distortion and fast settling make it ideal for buffer high speed A-to-D converters.

The AD8001 offers low power of 5.5 mA max (V_S = ±5 V) and can run on a single +12 V power supply, while being capable of delivering up to 70 mA of load current. All this is offered in a small 8-pin DIP or 8-pin SOIC package. These features make this amplifier ideal for portable and battery powered applications where size and power is critical.

The outstanding bandwidth of 800 MHz along with 1200 V/μs of slew rate make the AD8001 useful in many general purpose high speed applications where dual power supplies of up to ±6 V and single supplies from 6 V to 12 V are needed. The AD8001 is available in the industrial temperature range of –40°C to +85°C.

MAXIMUM POWER DISSIPATION

The maximum power that can be safely dissipated by the AD8001 is limited by the associated rise in junction temperature. The maximum safe junction temperature for plastic encapsulated devices is determined by the glass transition temperature of the plastic, approximately +150°C. Exceeding this limit temporarily may cause a shift in parametric performance due to a change in the stresses exerted on the die by the package. Exceeding a junction temperature of +175°C for an extended period can result in device failure.

While the AD8001 is internally short circuit protected, this may not be sufficient to guarantee that the maximum junction temperature (+150°C) is not exceeded under all conditions. To ensure proper operation, it is necessary to observe the maximum power derating curves.

[2]Standard Military Drawing Device. Ordering Number TBD. Contact our local sales office, representative or distributor for availability.
[3]Refer to Evaluation Board section.

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the AD8001 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

THEORY OF OPERATION

A very simple analysis can put the operation of the AD8001, a current feedback amplifier, in familiar terms. Being a current feedback amplifier, the AD8001's open-loop behavior is expressed as transimpedance, $\Delta V_O/\Delta I_{-IN}$, or T_Z. The open loop transimpedance behaves just as the open loop voltage gain of a voltage feedback amplifier, that is, it has a large dc value and decreases at roughly 6 dB/octave in frequency.

Since the R_{IN} is proportional to $1/g_M$, the equivalent voltage gain is just $T_Z \times g_M$, where the g_M in question is the transconductance of the input stage. This results in a low open loop input impedance at the inverting input, a now familiar result. Using this amplifier as a follower with gain, Figure 40, basic analysis yields the following result.

$$\frac{V_O}{V_{IN}} = G \times \frac{T_Z(S)}{T_Z(S) + G \times R_{IN} + R_1}$$

$$G = 1 + \frac{R_1}{R_2} \qquad R_{IN} = 1/g_M \approx 50\ \Omega$$

Recognizing that $G \times R_{IN} << R_1$ for low gains, it can be seen to the first order that bandwidth for this amplifier is independent of gain (G). This simple analysis in conjunction with Figure 41 in fact can predict the behavior of the AD8001 over a wide range of conditions.

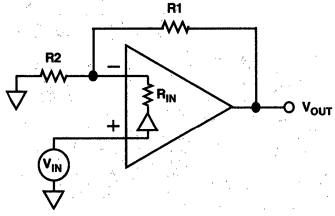

Figure 40.

Considering that additional poles contribute excess phase at high frequencies there is a minimum feedback resistance below which peaking or oscillation may result. This fact is used to determine the optimum feedback resistance, R_F. In practice parasitic capacitance at Pin 2 will also add phase in the feedback loop, so picking an optimum value for R_F can be difficult. Figure 42 illustrates this problem. Here the fine scale (0.1 dB/div) flatness is plotted vs. feedback resistance. These plots were taken using an evaluation card which is available to customers so that these results may readily duplicated (see Evaluation Board section).

Achieving and maintaining gain flatness of better than 0.1 dB at frequencies above 10 MHz requires careful consideration of several issues.

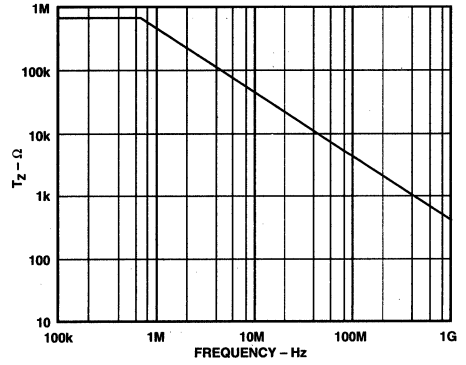

Figure 41. Transimpedance vs. Frequency

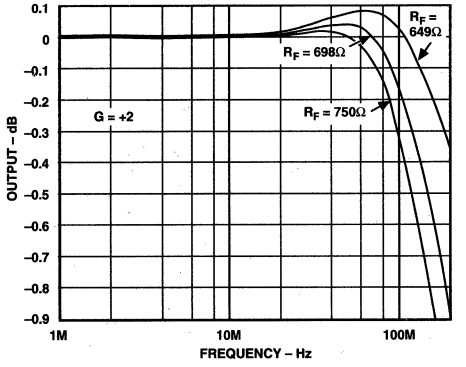

Figure 42. 0.1 dB Flatness vs. Frequency

Choice of Feedback and Gain Resistors

Because of the above mentioned relationship between the bandwidth and the feedback resistor, the fine scale gain flatness will, to some extent, vary with feedback resistance. It, therefore, is recommended that once optimum resistor values have been determined, 1% tolerance values should be used if it is desired to maintain flatness over a wide range of production lots. In addition, resistors of different construction have different associated parasitic capacitance and inductance. Surface mount resistors were used for the bulk of the characterization for this data sheet. It is not recommended that leaded components be used with the AD8001.

Printed Circuit Board Layout Considerations

As to be expected for a wideband amplifier, PC board parasitics can affect the overall closed loop performance. Of concern are stray capacitances at the output and the inverting input nodes. If a ground plane is to be used on the same side of the board as the signal traces, a space (5 mm min) should be left around the signal lines to minimize coupling. Additionally, signal lines connecting the feedback and gain resistors should be short enough so that their associated inductance does not cause high frequency gain errors. Line lengths on the order of less than 5 mm are recommended. If long runs of coaxial cable are being driven, dispersion and loss must be considered.

Power Supply Bypassing

Adequate power supply bypassing can be critical when optimizing the performance of a high frequency circuit. Inductance in the power supply leads can form resonant circuits that produce peaking in the amplifier's response. In addition, if large current transients must be delivered to the load, then bypass capacitors (typically greater than 1 µF) will be required to provide the best settling time and lowest distortion. A parallel combination at least 4.7 µF and between 0.1 µF and 0.01 µF is recommended. Some brands of electrolyic capacitors will require a small series damping resistor ≈4.7 Ω for optimum results.

DC Errors and Noise

There are three major noise and offset terms to consider in a current feedback amplifier. For offset errors refer to the equation below. For noise error the terms are root-sum-squared to give a net output error. In the circuit below (Figure 43) they are input offset (V_{IO}) which appears at the output multiplied by the noise gain of the circuit ($1 + R_F/R_I$), Noninverting input current ($I_{BN} \times R_N$) also multiplied by the noise gain, and the inverting input current, which when divided between R_F and R_I and subsequently multiplied by the noise gain always appears at the output as $I_{BN} \times R_F$. The input voltage noise of the AD8001 is a low 2 nV/√Hz. At low gains though the inverting input current noise times R_F is the dominant noise source. Careful layout and device matching contribute to better offset and drift specifications for the AD8001 compared to many other current feedback amplifiers. The typical performance curves in conjunction with the equations below can be used to predict the performance of the AD8001 in any application.

$$V_{OUT} = V_{IO} \times \left(1 + \frac{R_F}{R_I}\right) \pm I_{BN} \times R_N \times \left(1 + \frac{R_F}{R_I}\right) \pm I_{BI} \times R_F$$

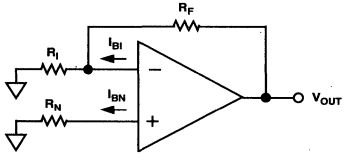

Figure 43. Output Offset Voltage

Driving Capacitive Loads

The AD8001 was designed primarily to drive nonreactive loads. If driving loads with a capacitive component is desired, best frequency response is obtained by the addition of a small series resistance as shown in Figure 44. The accompanying graph shows the optimum value for R_{SERIES} vs. capacitive load. It is worth noting that the frequency response of the circuit when driving large capacitive loads will be dominated by the passive roll-off of R_{SERIES} and C_L.

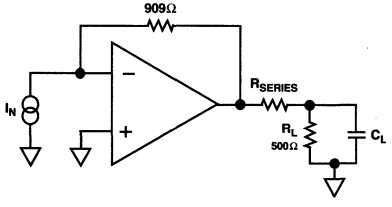

Figure 44. Driving Capacitive Loads

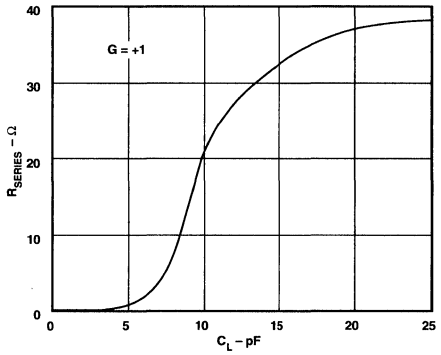

Figure 45. Recommended R_{SERIES} vs. Capacitive Load

Communications

Distortion is a key specification in communications applications. Intermodulation distortion (IMD) is a measure of the ability of an amplifier to pass complex signals without the generation of spurious harmonics. The third order products are usually the most problematic since several of them fall near the fundamentals and do not lend themselves to filtering. Theory predicts that the third order harmonic distortion components increase in power at three times the rate of the fundamental tones. The specification of third order intercept as the virtual point where fundamental and harmonic power are equal is one standard measure of distortion performance. Op amps used in closed-loop applications do not always obey this simple theory. At a gain of two the AD8001 has performance summarized in Figure 46. Here the worst third order products are plotted vs. input power. The third order intercept of the AD8001 is +33 dBm at 10 MHz.

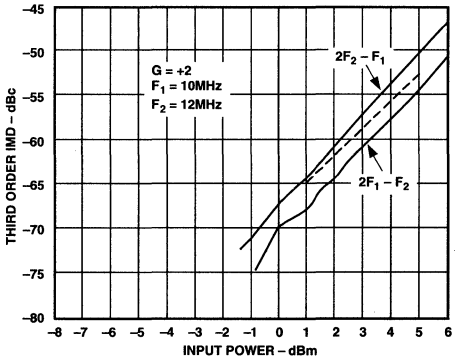

Figure 46. Third Order IMD; F_1 = 10 MHz, F_2 = 12 MHz

Operation as a Video Line Driver

The AD8001 has been designed to offer outstanding performance as a video line driver. The important specifications of differential gain (0.01%) and differential phase (0.025°) meet the most exacting HDTV demands for driving one video load. The AD8001 also drives up to two back terminated loads, as shown in Figure 47, with equally impressive performance (0.01%, 0.07°). Another important consideration is isolation between loads in a multiple load application. The AD8001 has more than 40 dB of isolation at 5 MHz when driving two 75 Ω back terminated loads.

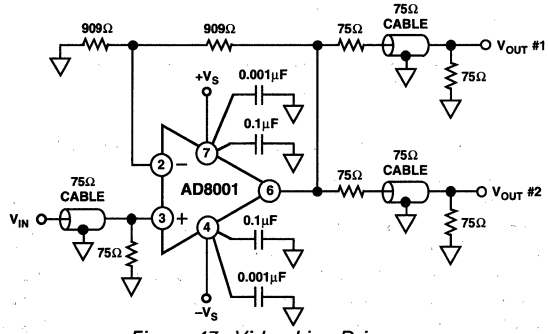

Figure 47. Video Line Driver

Driving A-to-D Converters

The AD8001 is well suited for driving high speed analog-to-digital converters such as the AD9058. The AD9058 is a dual 8-bit 50 Msps ADC. In the circuit below two AD8001s are shown driving the inputs of the AD9058 which are configured for 0 V to +2 V ranges. Bipolar input signals are buffered, amplified (–2×), and offset (by +1.0 V) into the proper input range of the ADC. Using the AD9058's internal +2 V reference connected to both ADCs as shown in Figure 48 reduces the number of external components required to create a complete data acquisition system. The 20 Ω resistors in series with ADC input are used to help the AD8001s drive the 10 pF ADC input capacitance. The two AD8001s only add 100 mW to the power consumption while not limiting the performance of the circuit

Layout Considerations

The specified high speed performance of the AD8001 requires careful attention to board layout and component selection. Proper RF design techniques and low parasitic component selection are mandatory.

The PCB should have a ground plane covering all unused portions of the component side of the board to provide a low impedance ground path. The ground plane should be removed from the area near the input pins to reduce stray capacitance.

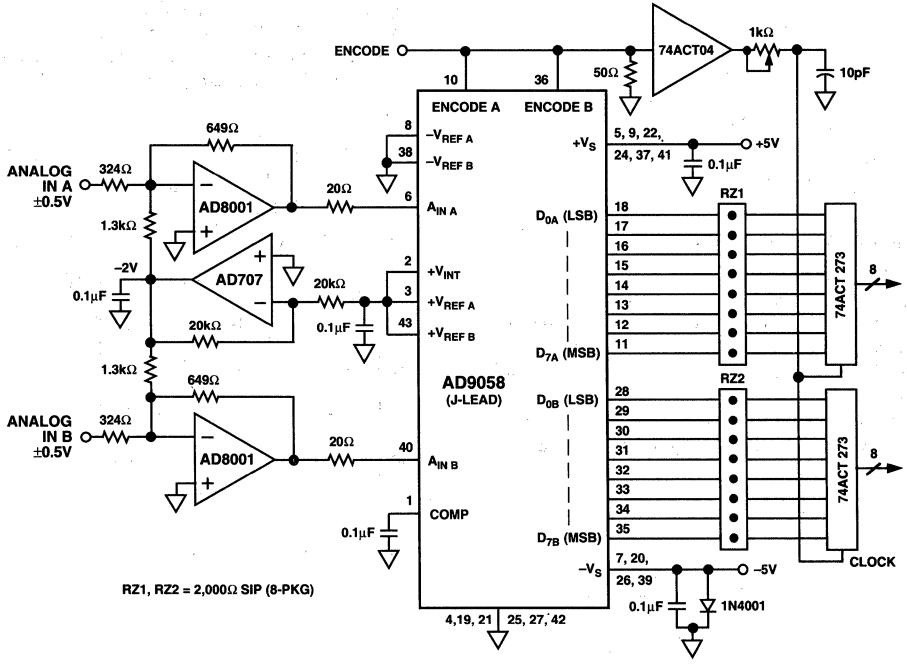

Figure 48. AD8001 Driving a Dual A-to-D Converter

Chip capacitors should be used for supply bypassing (see Figure 49). One end should be connected to the ground plane and the other within 1/8 in. of each power pin. An additional large (4.7 µF–10 µF) tantalum electrolytic capacitor should be connected in parallel, but not necessarily so close, to supply current for fast, large-signal changes at the output.

The feedback resistor should be located close to the inverting input pin in order to keep the stray capacitance at this node to a minimum. Capacitance variations of less than 1 pF at the inverting input will significantly affect high speed performance.

Stripline design techniques should be used for long signal traces (greater than about 1 in.). These should be designed with a characteristic impedance of 50 Ω or 75 Ω and be properly terminated at each end.

Evaluation Board

An evaluation board for the AD8001 is available that has been carefully laid-out and tested to demonstrate that the specified high speed performance of the device can be realized. For ordering information, please refer to the Ordering Guide.

The layout of the evaluation board can be used as shown or serve as a guide for a board layout.

Dual 800 MHz, 50 mW Current Feedback Amplifier

AD8002

FEATURES

Excellent Video Specifications (R_L = 150 Ω, G = +2)
- Gain Flatness 0.1 dB to 100 MHz
- 0.01% Differential Gain Error
- 0.025° Differential Phase Error

Low Power
- 5.5 mA/Amp max Power Supply Current (55 mW)

High Speed and Fast Settling
- 880 MHz, –3 dB Bandwidth (G = +1)
- 440 MHz, –3 dB Bandwidth (G = +2)
- 1200 V/μs Slew Rate
- 10 ns Settling Time to 0.1%

Low Distortion
- –65 dBc THD, f_C = 5 MHz
- 33 dBm 3rd Order Intercept, F_1 = 10 MHz
- –66 dB SFDR, f = 5 MHz
- –60 dB Crosstalk, f = 5 MHz

High Output Drive
- 70 mA Output Current
- Drives Up to 8 Back-Terminated Loads (75 Ω Each) While Maintaining Good Differential Gain/Phase Performance (0.05%/0.25°)

Available in Small 8-Pin PDIP or SOIC

APPLICATIONS

A-to-D Driver
Video Line Driver
Professional Cameras
Video Switchers
Special Effects
RF Receivers

PRODUCT DESCRIPTION

The AD8002 is a dual, low power, high speed amplifier designed to operate on ±5 V supplies. The AD8002 features unique transimpedance linearization circuitry. This allows it to drive video loads with excellent differential gain and phase performance on only 50 mW of power per amplifier. The AD8002 is a current feedback amplifier and features gain flatness of 0.1 dB to 100 MHz while offering differential gain and phase error of 0.01% and 0.025°. This makes the AD8002 ideal for professional video electronics such as cameras and video switchers. Additionally, the AD8002's low distortion and fast settling make it ideal for buffer high speed A-to-D converters.

The AD8002 offers low power of 5.5 mA/amplifier max (V_S = ±5 V) and can run on a single +12 V power supply, while being capable of delivering up to 70 mA of load current. All this is offered in a small 8-pin DIP or 8-pin SOIC package. These features make this amplifier ideal for portable and battery powered applications where size and power is critical.

The outstanding bandwidth of 800 MHz along with 1200 V/μs of slew rate make the AD8002 useful in many general purpose high speed applications where dual power supplies of up to ±6 V and single supplies from 6 V to 12 V are needed. The AD8002 is available in the industrial temperature range of –40°C to +85°C.

AD8002AN	–40°C to +85°C	8-Pin Plastic DIP
AD8002AR	–40°C to +85°C	8-Pin Plastic SOIC

*For outline information see Package Information section.

MAXIMUM POWER DISSIPATION

The maximum power that can be safely dissipated by the AD8002 is limited by the associated rise in junction temperature. The maximum safe junction temperature for plastic encapsulated devices is determined by the glass transition temperature of the plastic, approximately +150°C. Exceeding this limit temporarily may cause a shift in parametric performance due to a change in the stresses exerted on the die by the package. Exceeding a junction temperature of +175°C for an extended period can result in device failure.

While the AD8002 is internally short circuit protected, this may not be sufficient to guarantee that the maximum junction temperature (+150°C) is not exceeded under all conditions. To ensure proper operation, it is necessary to observe the maximum power derating curves.

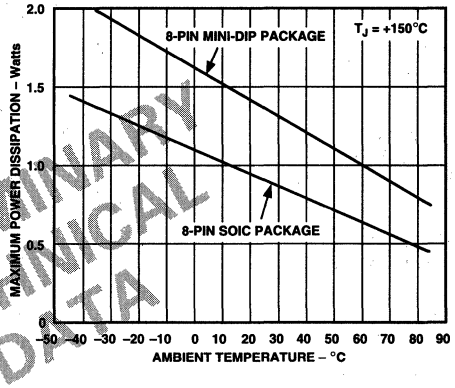

Figure 3. Plot of Maximum Power Dissipation vs. Temperature

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the AD8002 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

THEORY OF OPERATION

A very simple analysis can put the operation of the AD8002, a current feedback amplifier, in familiar terms. Being a current feedback amplifier, the AD8002's open-loop behavior is expressed as transimpedance, $\Delta V_O/\Delta I_{-IN}$, or T_Z. The open loop transimpedance behaves just as the open loop voltage gain of a voltage feedback amplifier, that is, it has a large dc value and decreases at roughly 6 dB/octave in frequency.

Since the R_{IN} is proportional to $1/g_M$, the equivalent voltage gain is just $T_Z \times g_M$, where the g_M in question is the transconductance of the input stage. This results in a low open loop input impedance at the inverting input, a now familiar result. Using this amplifier as a follower with gain, Figure 40, basic analysis yields the following result.

$$\frac{V_O}{V_{IN}} = G \times \frac{T_Z(S)}{T_Z(S) + G \times R_{IN} + R_1}$$

$$G = 1 + \frac{R_1}{R_2} \qquad R_{IN} = 1/g_M \approx 50\ \Omega$$

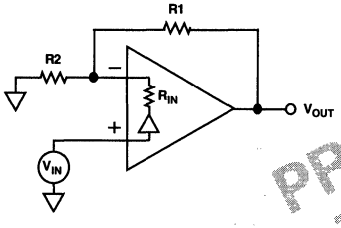

Figure 40.

Recognizing that $G \times R_{IN} << R_1$ for low gains, it can be seen to the first order that bandwidth for this amplifier is independent of gain (G). This simple analysis in conjunction with Figure 41 in fact can predict the behavior of the AD8002 over a wide range of conditions.

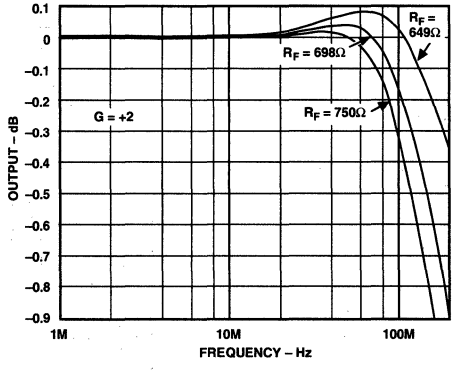

Figure 41. Frequency Response, G = +2

Considering that additional poles contribute excess phase at high frequencies there is a minimum feedback resistance below which peaking or oscillation may result. This fact is used to determine the optimum feedback resistance, R_F. In practice parasitic capacitance at Pin 2 will also add phase in the feedback loop, so picking an optimum value for R_F can be difficult. Figure 42 illustrates this problem. Here the fine scale (0.1 dB/div) flatness is plotted vs. feedback resistance.

Achieving and maintaining gain flatness of better than 0.1 dB at frequencies above 10 MHz requires careful consideration of several issues.

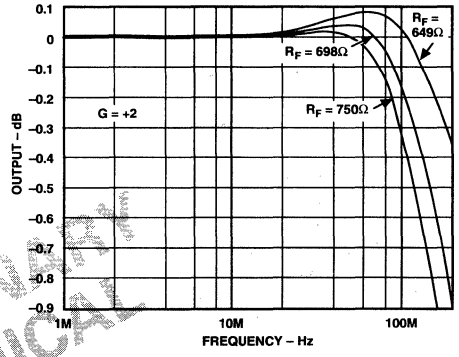

Figure 42. 0.1 dB Flatness vs. Frequency, G = +2

Choice of Feedback and Gain Resistors

Because of the above mentioned relationship between the bandwidth and the feedback resistor, the fine scale gain flatness will, to some extent, vary with feedback resistance. It, therefore, is recommended that once optimum resistor values have been determined, 1% tolerance values should be used if it is desired to maintain flatness over a wide range of production lots. In addition, resistors of different construction have different associated parasitic capacitance and inductance. Surface mount resistors were used for the bulk of the characterization for this data sheet. It is not recommended that leaded components be used with the AD8002.

Printed Circuit Board Layout Considerations

As to be expected for a wideband amplifier, PC board parasitics can affect the overall closed loop performance. Of concern are stray capacitances at the output and the inverting input nodes. If a ground plane is to be used on the same side of the board as the signal traces, a space (5 mm min) should be left around the signal lines to minimize coupling. Additionally, signal lines connecting the feedback and gain resistors should be short enough so that their associated inductance does not cause high frequency gain errors. Line lengths on the order of less than 5 mm are recommended. If long runs of coaxial cable are being driven, dispersion and loss must be considered.

Power Supply Bypassing

Adequate power supply bypassing can be critical when optimizing the performance of a high frequency circuit. Inductance in the power supply leads can form resonant circuits that produce peaking in the amplifier's response. In addition, if large current transients must be delivered to the load, then bypass capacitors (typically greater than 1 µF) will be required to provide the best settling time and lowest distortion. A parallel combination at least 4.7 µF and between 0.1 µF and 0.01 µF is recommended. Some brands of electrolyic capacitors will require a small series damping resistor ≈4.7 Ω for optimum results.

DC Errors and Noise

There are three major noise and offset terms to consider in a current feedback amplifier. For offset errors refer to the equation below. For noise error the terms are root-sum-squared to give a net output error. In the circuit below (Figure 43) they are input offset (V_{IO}) which appears at the output multiplied by the noise gain of the circuit ($1 + R_F/R_I$), Noninverting input current ($I_{BN} \times R_N$) also multiplied by the noise gain, and the inverting input current, which when divided between R_F and R_I and subsequently multiplied by the noise gain always appears at the output as $I_{BN} \times R_F$. The input voltage noise of the AD8002 is a low 2 nV/√Hz. At low gains though the inverting input current noise times R_F is the dominant noise source. Careful layout and device matching contribute to better offset and drift specifications for the AD8002 compared to many other current feedback amplifiers. The typical performance curves in conjunction with the equations below can be used to predict the performance of the AD8002 in any application.

$$V_{OUT} = V_{IO} \times \left(1 + \frac{R_F}{R_I}\right) \pm I_{BN} \times R_N \times \left(1 + \frac{R_F}{R_I}\right) \pm I_{BI} \times R_F$$

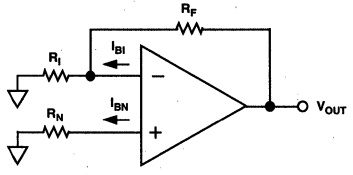

Figure 43. Output Offset Voltage

Driving Capacitive Loads

The AD8002 was designed primarily to drive nonreactive loads. If driving loads with a capacitive component is desired, best frequency response is obtained by the addition of a small series resistance as shown in Figure 44. The accompanying graph

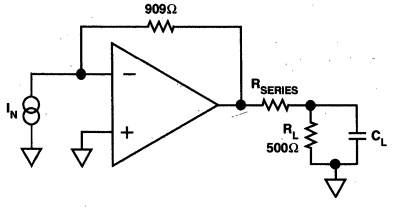

Figure 44. Driving Capacitive Loads

shows the optimum value for R_{SERIES} vs. capacitive load. It is worth noting that the frequency response of the circuit when driving large capacitive loads will be dominated by the passive roll-off of R_{SERIES} and C_L

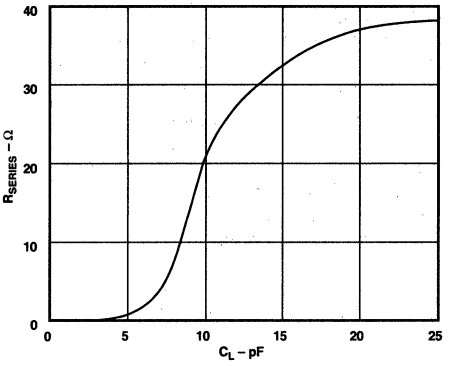

Figure 45. Recommended R_{SERIES} vs. Capacitive Load

Communications

Distortion is a key specification in communications applications. Intermodulation distortion (IMD) is a measure of the ability of an amplifier to pass complex signals without the generation of spurious harmonics. The third order products are usually the most problematic since several of them fall near the fundamentals and do not lend themselves to filtering. Theory predicts that the third order harmonic distortion components increase in power at three times the rate of the fundamental tones. The specification of third order intercept as the virtual point where fundamental and harmonic power are equal is one standard measure of distortion performance. Op amps used in closed-loop applications do not always obey this simple theory. At a gain of two, the AD8002 has performance summarized in Figure 46. Here the worst third order products are plotted vs. input power. The third order intercept of the AD8002 is +33 dBm at 10 MHz.

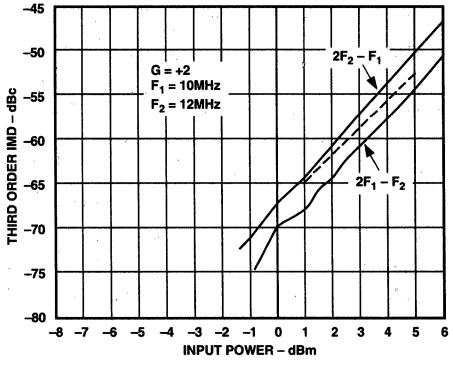

Figure 46. Third Order IMD; F_1 = 10 MHz, F_2 = 12 MHz

Operation as a Video Line Driver

The AD8002 has been designed to offer outstanding performance as a video line driver. The important specifications of differential gain (0.01%) and differential phase (0.025°) meet the most exacting HDTV demands for driving one video load with each amplifier. The AD8002 also drives up to four back terminated loads, as shown in Figure 47, with equally impressive performance. Another important consideration is isolation between loads in a multiple load application. The AD8002 has more than 40 dB of isolation at 5 MHz when driving two 75 Ω back terminated loads.

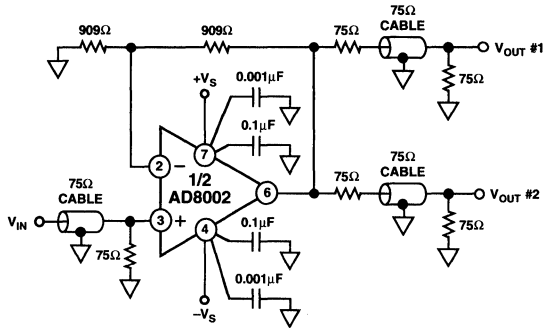

Figure 47. Video Line Driver

Driving A-to-D Converters

The AD8002 is well suited for driving high speed analog-to-digital converters such as the AD9058. The AD9058 is a dual 8-bit 50 Msps ADC. In the circuit below the AD8002 is shown driving the inputs of the AD9058 which are configured for 0 V to +2 V ranges. Bipolar input signals are buffered, amplified (–2×), and offset (by +1.0 V) into the proper input range of the ADC. Using the AD9058's internal +2 V reference connected to both ADCs as shown in Figure 48 reduces the number of external components required to create a complete data acquisition system. The 20 Ω resistors in series with ADC inputs are used to help the AD8002s drive the 10 pF ADC input capacitance. The two AD8002s only add 100 mW to the power consumption while not limiting the performance of the circuit.

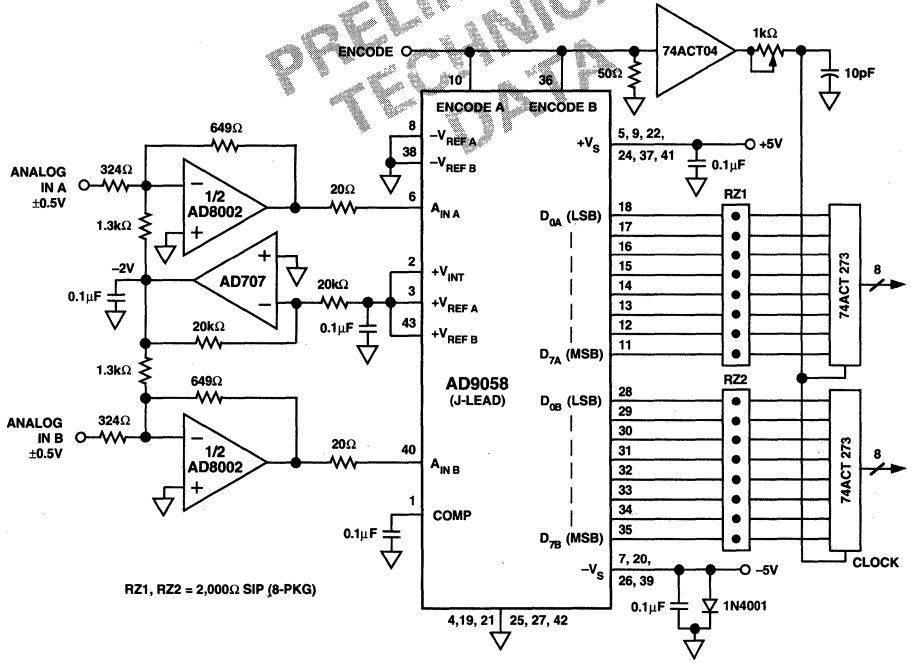

Figure 48. AD8002 Driving a Dual A-to-D Converter

Layout Considerations

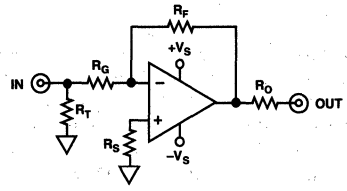
The specified high speed performance of the AD8002 requires careful attention to board layout and component selection. Proper RF design techniques and low parasitic component selection are mandatory.

The PCB should have a ground plane covering all unused portions of the component side of the board to provide a low impedance ground path. The ground plane should be removed from the area near the input pins to reduce stray capacitance.

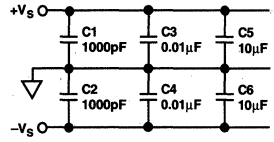
Chip capacitors should be used for supply bypassing (see Figure 49). One end should be connected to the ground plane and the other within 1/8 in. of each power pin. An additional large (4.7 µF–10 µF) tantalum electrolytic capacitor should be connected in parallel, but not necessarily so close, to supply current for fast, large-signal changes at the output.

The feedback resistor should be located close to the inverting input pin in order to keep the stray capacitance at this node to a minimum. Capacitance variations of less than 1 pF at the inverting input will significantly affect high speed performance.

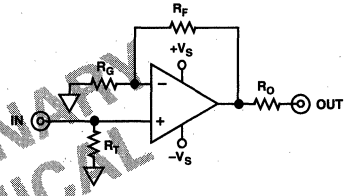
Stripline design techniques should be used for long signal traces (greater than about 1 in.). These should be designed with a characteristic impedance of 50 Ω or 75 Ω and be properly terminated at each end.



Inverting Configuration



Supply Bypassing



Noninverting Configuration

NOTES

*100 Ω resistor used in series with the noninverting input.

**90.9 Ω resistor used in series with the noninverting input.

Quad 3000 V/μs, 35 mW Current Feedback Amplifier

AD8004

FEATURES

High Speed
- 400 MHz –3 dB Bandwidth (G = +1)
- 3000 V/μs Slew Rate
- 10 ns Settling Time to 0.1%
- 0.9 ns Rise Time for 2 V Step

Low Power
- 3.5 mA/Amp Power Supply Current (35 mW/Amp)

Single Supply Operation
- Fully Specified for +5 V Supply

Great Video Specifications (R_L = 150 Ω, G = +2)
- Gain Flatness 0.1 dB to 30 MHz
- 0.05% Differential Gain Error
- 0.05° Differential Phase Error

Low Distortion
- –65 dBc THD at 10 MHz
- 33 dBm Third Order Intercept, f = 10 MHz
- –65 dB SFDR, f = 20 MHz

High Output Current of 50 mA

Available in a Small 14-Pin PDIP and SOIC

APPLICATIONS

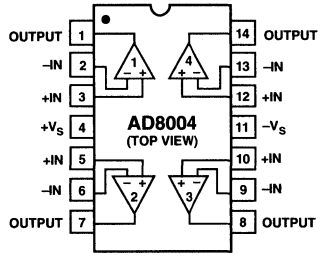
Image Scanners

Active Filters

Video Switchers

Special Effects

FUNCTIONAL BLOCK DIAGRAM



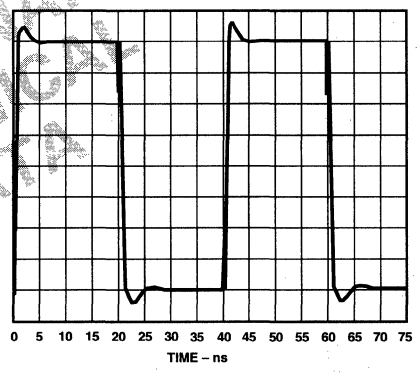


Figure 1. 4 V Step Response of AD8004

PRODUCT DESCRIPTION

The AD8004 is a quad, low power, high speed amplifier designed to operate on +5 V or ±5 V supplies. It utilizes a current feedback architecture and features high slew rate of 3000 V/μs making the AD8004 ideal for handling large amplitude pulses. Additionally, the AD8004 provides gain flatness of 0.1 dB to 30 MHz while offering differential gain and phase error of 0.05% and 0.05°. This makes the AD8004 suitable for professional video electronics such as cameras and video switchers.

The AD8004 offers low power of 3.5 mA/amplifier and can run on a single +5 V or +12 V power supply, while being capable of delivering up to 50 mA of load current. All this is offered in a small 14-pin DIP or 14-pin SOIC package. These features make this amplifier ideal for portable and battery powered applications where size and power is critical.

The outstanding bandwidth of 400 MHz along with 3000 V/μs of slew rate make the AD8004 useful in many general purpose high speed applications where dual power supplies of up to ±6 V and single supplies from 5 V to 12 V are needed. The AD8004 is available in the industrial temperature range of –40°C to +85°C.

This is a preliminary data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

AD8004AN	–40°C to +85°C	14-Pin Plastic DIP	N-14
AD8004AR	–40°C to +85°C	14-Pin Plastic SOIC	R-14

*For outline information see Package Information section.

MAXIMUM POWER DISSIPATION

The maximum power that can be safely dissipated by the AD8004 is limited by the associated rise in junction temperature. The maximum safe junction temperature for plastic encapsulated devices is determined by the glass transition temperature of the plastic, approximately +150°C. Exceeding this limit temporarily may cause a shift in parametric performance due to a change in the stresses exerted on the die by the package. Exceeding a junction temperature of +175°C for an extended period can result in device failure.

While the AD8004 is internally short circuit protected, this may not be sufficient to guarantee that the maximum junction temperature (+150°C) is not exceeded under all conditions. To ensure proper operation, it is necessary to observe the maximum power derating curve below.

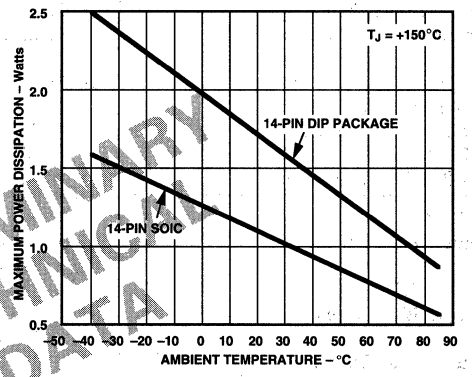

Figure 2. Maximum Power Dissipation vs. Ambient Temperature

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the AD8004 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

Low Distortion, Wide Bandwidth Voltage Feedback Clamp Amps

AD8036/AD8037

FEATURES

Superb Clamping Characteristics
- **<25 mV Clamp Accuracy**
- **3 ns Overdrive Recovery**
- **Minimized Nonlinear Clamping Region**

Wide Bandwidth	**AD8036**	**AD8037**
Small Signal	**350 MHz**	**240 MHz**
Large Signal (4 V p-p)	**200 MHz**	**150 MHz**

Good DC Characteristics
- **2 mV Offset**
- **10 μV/°C Drift**

Ultralow Distortion, Low Noise
- **–90 dBc typ @ 5 MHz**
- **–64 dBc typ @ 20 MHz**
- **5.6 nV/√Hz Spectral Noise Density**

High Speed
- **Slew Rate 1600 V/μs**
- **Settling 11 ns to 0.1%, 16 ns to 0.01%**

±3 V to ± 5 V Supply Operation

APPLICATIONS
- **ADC Buffer**
- **IF/RF Signal Processing**
- **High Quality Imaging**
- **Broadcast Video Systems**
- **Video Amplifier**

PRODUCT DESCRIPTION

The AD8036 and AD8037 are very high speed and wide bandwidth input clamping amplifiers. The AD8036 is unity-gain stable. The AD8037 is stable at a gain of two. Utilizing proprietary input clamping architecture, the AD8036 and AD8037 offer unparalleled clamp amp performance. Also, utilizing a voltage feedback architecture, their exceptional settling time, bandwidth, and low distortion performance meet the requirements of many applications that previously depended on current feedback amplifiers. Their classical op amp structure works much more predictably in many designs. This product can be used as a classical op amp or a clamp amp where a high and low output voltage is specified.

A proprietary design architecture has produced an amplifier that combines many of the best characteristics of both current feedback and voltage feedback amplifiers. The AD8036 and AD8037 exhibit exceptionally fast and accurate pulse response (16 ns to 0.01%) as well as extremely wide small signal and large signal bandwidth and ultralow distortion. The AD8036 achieves –68 dBc at 20 MHz with 350 MHz small signal and 200 MHz large signal bandwidths. The AD8036 and AD8037's clamp accuracy is 25 mV or less and it recovers from overdrive within 2 ns.

These characteristics position the AD8036/AD8037 ideally for driving as well as buffering flash and high resolution ADCs. Additionally, nonlinear functions with high speed and wide bandwidth are made possible by the balanced high impedance inputs of the voltage feedback architecture.

The AD8036 is offered in industrial (–40°C to +85°C) and military (–55°C to +125°C) temperature ranges and the AD8037 in industrial. Industrial versions are available in plastic DIP and SOIC; MIL versions are packaged in cerdip.

NOTES
[1]Absolute maximum ratings are limiting values to be applied individually, and beyond which the serviceability of the circuit may be impaired. Functional operability is not necessarily implied. Exposure to absolute maximum rating conditions for an extended period of time may affect device reliability.
[2]Output is short-circuit protected to ground, but not to supplies. Continuous short circuit to ground may affect device reliability.
[3]Typical thermal impedances (part soldered onto board; no air flow):
Ceramic DIP: $\theta_{JA} = 110°C/W$; $\theta_{JC} = 20°C/W$
Plastic SOIC: $\theta_{JA} = 150°C/W$; $\theta_{JC} = 30°C/W$
Plastic DIP: $\theta_{JA} = 140°C/W$; $\theta_{JC} = 30°C/W$.
[4]Temperature shown is for surface mount devices, mounted by vapor phase soldering. Through-hole devices (ceramic and plastic DIPs) can be soldered at +300°C for 10 seconds.

*N = Plastic DIP; Q = Cerdip; R = SOIC (Small Outline Integrated Circuit.) For outline information see Package Information section.

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although these devices feature proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

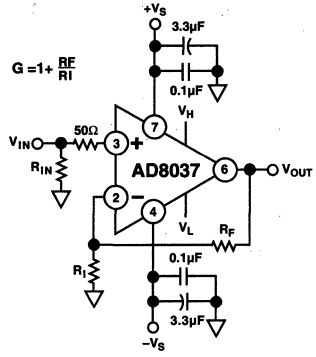

Figure 2. Noninverting Operation

Clamp Operation

The AD8036/AD8037 have built-in input clamps that can be used to protect sensitive devices connected to the amplifier output. Clamp operation can only be performed in the noninverting configuration. By utilizing input clamps, the maximum linear range is achieved in conjunction with the highest clamp accuracy.

The clamp voltages (high and low) are connected to pins V_{HIGH} (input) and V_{LOW} (input) accordingly. These are high *impedance* nodes with minimal current drawn. These input clamp voltages multiplied by the amplifier gain sets the limited output swing range. V_H (output) = V_H (input) × A_V and V_L (output) = V_L (input) × A_V. The chart on the cover page shows the characteristics of the AD8036/AD8037 in clamped operation versus competitors who use output clamping techniques. The improved accuracy and hard clamping characteristics of the AD8036/AD8037 allow clamps to be used in applications where output clamps cannot be used. Also, the recovery from overdrive will be 1 ns typical.

The proprietary input clamp architecture has also been designed to minimize signal distortion as you approach the clamp voltages. This characteristic is fundamental to the signal integrity in the clamp region and allows for maximum useful amplifier range. Figure 3 shows the distortion of the AD8037 as you approach a high clamp voltage value of 1 V versus the competitors.

In addition, the clamp voltage range is only limited by the output voltage range (±3.4 V), and the clamp voltages can be set to any value between the ±3.4 V swing. Of course, the clamps can be set beyond the output voltage swing, but then the output will not be limited by the clamp voltages, but by the swing range. Output clamps typically have limited clamp voltage settings and cannot be set to any voltage between $\pm V_{CC}$. For example, it is typical that a low clamp voltage can be set only as high as +2 V, and the high clamp voltage as low as –2 V. This can be a limiting feature in many applications.

The AD8036/AD8037 have been designed with internal ties from the clamp voltage pins to $\pm V_{CC}$, and if the clamp pins are left floating, the low clamp voltage (V_L) will be set to $-V_{CC}$ and the high clamp voltage (V_H) will be set to $+V_{CC}$. In this configuration, the AD8036/AD8037 will perform as a standard operational amplifier and will not clamp the output.

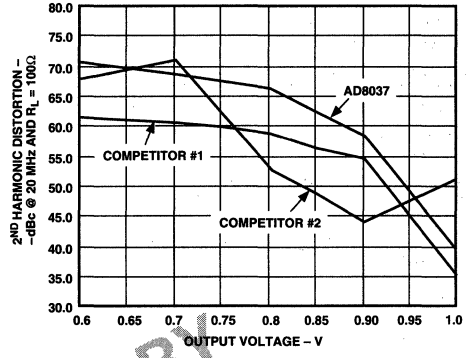

Figure 3. Distortion Near Clamp Values

Layout Considerations

The specified high speed performance of the AD8036/AD8037 requires careful attention to board layout and component selection. Proper RF design techniques and low-pass parasitic component selection are mandatory.

The PCB should have a ground plane covering all unused portions of the component side of the board to provide a low impedance path. The ground plane should be removed from the area near the input pins to reduce the stray capacitance.

Chip capacitors should be used for the supply bypassing (see Figure 2). One end should be connected to the ground plane and the other within 1/8 inch of each power pin. An additional large (0.47 µF–10 µF) tantalum electrolytic capacitor should be connected in parallel, but not necessarily so close, to supply current for fast, large signal changes at the output.

The feedback resistor should be located close to the inverting input pin in order to keep the stray capacitance at this node to a minimum. Capacitance variations of less than 1 pF at the inverting input will significantly affect high speed performance.

Stripline design techniques should be used for long signal traces (greater than about 1 inch). These should be designed with a characteristic impedance of 50 Ω or 75 Ω and be properly terminated at each end.

Evaluation Board

An evaluation board for the AD8036 is available that has been carefully laid-out and tested to demonstrate that the specified high speed performance of the device can be realized. For ordering information, please refer to the ordering guide.

The layout of the evaluation board can be used as shown or serve as a guide for a board layout.

Table I.

Component	AD8036AN (DIP) Gain					AD8036AR (SOIC) Gain

Supply Bypassing

Figure 4. Noninverting Configuration for Evaluation Boards

A Diodeless, High Speed, Full-Wave Rectifier

A high speed, full-wave rectifier (or absolute-value amplifier) circuit using high speed, clamping amplifiers is shown in Figure 5. This circuit topology provides both speed and performance enhancements over the traditional diode-based topologies that contain diodes in the amplifier feedback path. These diode-based topologies have performance limitations at both lower signal input levels and higher bandwidths. One limitation is due to the increase in dynamic resistance of the diode that reduces the amount of feedback at lower signal levels. Another limitation is due to the reduction of the amplifier's open-loop gain at higher frequencies which is required to over come the forward-bias voltage drop of the diode. These limitations are most visible at the zero crossings of the input signal when the diodes must change states.

This circuit in Figure 5 consists of three high speed, clamping amplifiers (U1–U3: AD8037) along with 1% metal-film resistors used for gain control and input bias current compensation. The high speed, clamp accuracy and large signal bandwidth of the AD8037 make this application feasible. They can accurately clamp the input signal within 5 ns to a user defined level. Since the internal clamping circuitry of these amplifiers is located within their input stages, these amplifiers can clamp only in the noninverting mode. In this circuit, only U2 is configured as a clamping amplifier while U1 and U3 function as a buffer and difference amplifier, respectively.

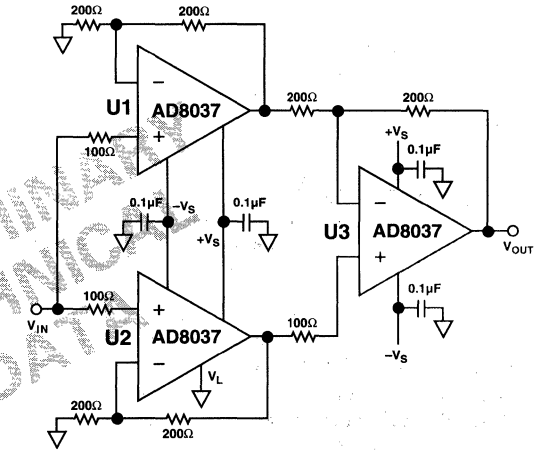

Figure 5.

The circuit is configured for positive full-wave rectification by configuring U2 as a gain-of-two, positive half-wave rectifier. This is accomplished by setting the positive clamping threshold level (Pin 8 of U2) to the positive supply (hence, outside the input voltage range of the amplifiers input) and the negative clamping threshold level (Pin 5 of U2) to ground. For negative full-wave rectification, U2 must be configured as a gain-of-two, negative half-wave rectifier by setting the positive clamping threshold level to ground and the negative clamping threshold level to the negative supply. U1 is simply configured as a gain of two buffer and is required to buffer the input signal source, V_{IN}, from the dynamic input impedance presented by U3 as well as match the signal delay of U2. U3 subtracts the output of the half-wave rectifier (U2) from the buffer output (U1) to produce the desired gain-of-two full-wave rectification. An optional trim network consisting of a potentiometer can be used to trim out any clamping offset error of U2. Precision 1% resistors for the gain controlling elements of U1 and U2 will typically maintain under 2% gain accuracy while values under 250 Ω will not degrade the phase margin of these high speed amplifiers.

Low Distortion, Precision, Wide Bandwidth Op Amp

AD9617*

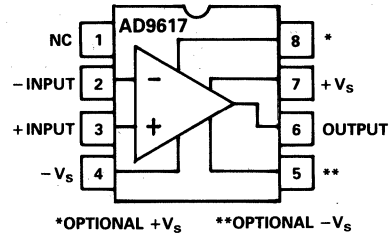
FEATURES

Usable Closed-Loop Gain Range: ±1 to ±40
Low Distortion: −67 dBc (2nd) at 20 MHz
Small Signal Bandwidth: 190 MHz (A_V = +3)
Large Signal Bandwidth: 150 MHz at 4 V p-p
Settling Time: 10 ns to 0.1%; 14 ns to 0.02%
Overdrive and Output Short Circuit Protected
Fast Overdrive Recovery
DC Nonlinearity 10 ppm

APPLICATIONS

Driving Flash Converters
D/A Current-to-Voltage Converters
IF, Radar Processors
Baseband and Video Communications
Photodiode, CCD Preamps

PIN CONFIGURATION



*OPTIONAL $+V_S$ **OPTIONAL $-V_S$

NOTE: FOR BEST SETTLING TIME AND DISTORTION PERFORMANCE, USE OPTIONAL SUPPLY CONNECTIONS. PERFORMANCE INDICATED IN SPECIFICATIONS IS BASED ON SUPPLY CONNECTIONS TO THESE PINS.

GENERAL DESCRIPTION

The AD9617 is a current feedback amplifier which utilizes a proprietary architecture to produce superior distortion and dc precision. It achieves this along with fast settling, very fast slew rate, wide bandwidth (both small signal and large signal) and exceptional signal fidelity. The device achieves −67 dBc 2nd harmonic distortion at 20 MHz while maintaining 190 MHz small signal and 150 MHz large signal bandwidths.

These attributes position the AD9617 as an ideal choice for driving flash ADCs and buffering the latest generation of DACs. Optimized for applications requiring gain between ±1 to ±15, the AD9617 is unity gain stable without external compensation.

Additional benefits of the AD9617B and T grades include input offset voltage of 500 μV and temperature coefficient (TC) of 3 μV/°C. These accuracy performance levels make the AD9617 an excellent choice for driving emerging high resolution (12–16 bits), high speed analog-to-digital converters and flash converters.

The AD9617 offers outstanding performance in high fidelity, wide bandwidth applications in instrumentation ranging from network and spectrum analyzers to oscilloscopes and in military systems such as radar, SIGINT, and ESM systems. The superior slew rate, low overshoot and fast settling of the AD9617 allow the device to be used in pulse applications such as communications receivers and high speed ATE. Most monolithic op amps suffer in these precision pulse applications due to slew rate limiting.

The AD9617J operates over the range of 0 to +70°C and is available in either an 8-pin plastic mini-DIP or an 8-lead plastic small outline package (SOIC). The AD9617A and B versions are rated over the industrial temperature range of −40°C to +85°C. The AD9617S and T versions are rated over the military temperature range of −55°C to +125°C and are available processed to MIL-STD-883B.

NOTES

[1]Absolute maximum ratings are limiting values to be applied individually and beyond which the serviceability of the circuit may be impaired. Functional operability is not necessarily implied. Exposure to absolute maximum rating conditions for an extended period of time may affect device reliability.

[2]Output is short circuit protected to ground, but not to supplies. Continuous short circuit to ground may affect device reliability.

[3]Typical thermal impedances (part soldered onto board):
Mini-DIP: θ_{JA} = 140°C/W; θ_{JC} = 30°C/W. Side Brazed/Cerdip: θ_{JA} = 110°C/W; θ_{JC} = 20°C/W. SOIC Package: θ_{JA} = 150°C/W; θ_{JC} = 30°C/W.

[4]Measured with respect to the inverting input.

[5]Typical is defined as the mean of the distribution.

[6]Measured in voltage follower configuration.

[7]Measured with V_{IN} = ±0.25 V.

[8]Frequency = 4.3 MHz; R_L = 150 Ω; A_V = +3.

Specifications subject to change without notice.

EXPLANATION OF TEST LEVELS

Test Level

I – 100% production tested.

II – 100% production tested at +25°C and sample tested at specified temperatures. AC testing of J grade devices done on sample basis.

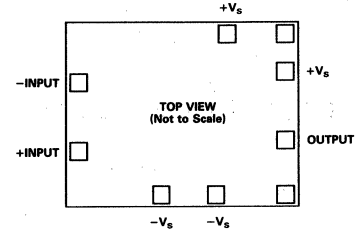
III – Sample tested only.

IV – Parameter is guaranteed by design and characterization testing.

V – Parameter is a typical value only.

VI – All devices are 100% production tested at +25°C. 100% production tested at temperature extremes for extended temperature devices; sample tested at temperature extremes for commercial/industrial devices.

Die Connections



DIE SIZE = 53 × 67 × 15 mils

NOTES
[1]Absolute maximum ratings are limiting values to be applied individually and beyond which the serviceability of the circuit may be impaired. Functional operability is not necessarily implied. Exposure to absolute maximum rating conditions for an extended period of time may affect device reliability.
[2]Output is short circuit protected to ground, but not to supplies. Continuous short circuit to ground may affect device reliability.
[3]Typical thermal impedances (part soldered onto board):
Mini-DIP: θ_{JA} = 140°C/W; θ_{JC} = 30°C/W.
Side Brazed/Cerdip: θ_{JA} = 110°C/W; θ_{JC} = 20°C/W.
SOIC Package: θ_{JA} = 150°C/W; θ_{JC} = 30°C/W.
[4]Measured with respect to the inverting input.
[5]Typical is defined as the mean of the distribution.
[6]Measured in voltage follower configuration.
[7]Measured with V_{IN} = ±0.25 V.
[8]Frequency = 4.3 MHz; R_L = 150 Ω; A_V = +10.
Specifications subject to change without notice.

EXPLANATION OF TEST LEVELS
Test Level
I – 100% production tested.
II – 100% production tested at +25°C and sample tested at specified temperatures. AC testing of J grade devices done on sample basis.
III – Sample tested only.
IV – Parameter is guaranteed by design and characterization testing.
V – Parameter is a typical value only.
VI – All devices are 100% production tested at +25°C. 100% production tested at temperature extremes for extended temperature devices; sample tested at temperature extremes for commercial/industrial devices.

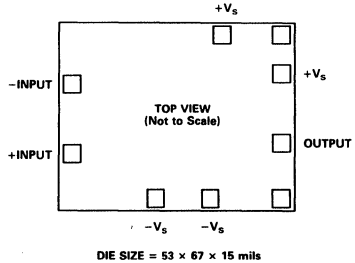
DIE CONNECTIONS



DIE SIZE = 53 × 67 × 15 mils

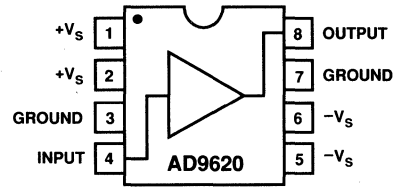
Ultralow Distortion, 600 MHz Buffer

AD9620*

FEATURES
Excellent Gain Accuracy: 0.994 V/V
Wide Bandwidth: 600 MHz
Slew Rate: 2200 V/μs
Ultralow Distortion:
−73 dBc @ 20 MHz
−91 dBc @ 2.3 MHz
Fast Settling Time: 8 ns to 0.02%
Low Noise: 2.0 nV/$\sqrt{Hz}$

APPLICATIONS
IF/Communications
Impedance Transformations
Drives Flash ADCs
Line Driving

DIP CONFIGURATION



NC = NO CONNECT

GENERAL DESCRIPTION

The AD9620 is a monolithic, unity gain buffer amplifier that sets new standards in gain accuracy, wide bandwidth and low distortion. Its large signal bandwidth, ultralow distortion over frequency, and drive capabilities of the AD9620 make this buffer an ideal driver for flash ADCs. Other applications which require increased current drive at unity voltage gain, such as cable driving, also benefit from the AD9620's performance.

In addition to innovative (patent pending) feedback architecture, special packaging techniques improve dynamic performance by minimizing the reactive effects associated with standard packages. The result is −73 dBc harmonic suppression at 20 MHz, and −91 dBc at 2.3 MHz. The AD9620 also outperforms other amplifiers, including its predecessor AD9630, in terms of small-signal pulse response and dc linearity. These features make the AD9620 the premier driver for high speed, high resolution ADCs.

Available in side-brazed ceramic DIP packages, the "A" suffix unit is guaranteed for −40°C to +85°C operating temperatures; the "S" suffix device is guaranteed from −55°C to +125°C. AD9620 die are dc tested at +25°C.

*Patent(s) Pending.

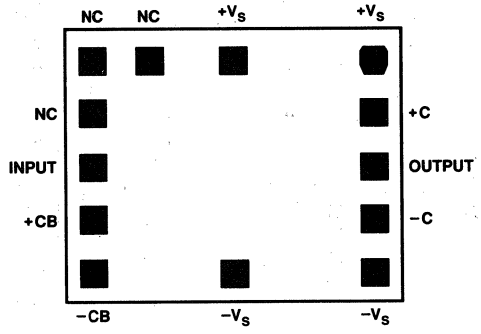
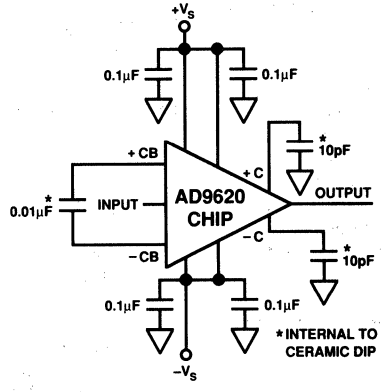
AD9620 DIE LAYOUT

60 (length) × 50 (width) × 15 (height) mils





AD9620 Bonding Diagram

THEORY OF OPERATION

The AD9620 is a wide bandwidth, unity gain buffer amplifier that utilizes innovative (patent pending) voltage feedback architecture. Large loop gain and high slew rate significantly improve dc linearity and large signal bandwidth when compared with that achieved with more conventional designs.

Its large-signal bandwidth compares favorably with competitive devices of open-loop design without their limitations. Open-loop devices often sacrifice dc linearity and introduce frequency distortion when driving low load impedances; the AD9620 does not. Its design yields low distortion products that are relatively constant for any resistive load greater than 50 ohms.

The AD9620 will satisfy any high performance analog signal processing application requiring isolation or current boosting between the signal source and load. Its combination of high input resistance and low capacitance, dc precision, and exceptional dynamic characteristics sets a new standard in performance that has no equal.

Excessive peaking may occur when using the AD9620 to directly drive loads with more than 3 pF of capacitance. To prevent this, a small value of resistance (R_S) should be placed in series with the buffer output.

ANALOG DEVICES

Wideband Voltage Feedback Amplifier

GENERAL DESCRIPTION

The AD9621 is one of a family of very high speed and wide bandwidth amplifiers utilizing a voltage feedback architecture. These amplifiers define a new level of performance for voltage feedback amplifiers, especially in the categories of large signal bandwidth, slew rate, settling, and low noise.

Proprietary design architectures have resulted in an amplifier family that combines the most attractive attributes of both current feedback and voltage feedback amplifiers. The AD9621 exhibits extraordinarily accurate and fast pulse response characteristics (7 ns settling to 0.1%) as well as extremely wide small and large signal bandwidth previously found only in current feedback amplifiers. When combined with balanced high impedance inputs and low input noise current more common to voltage feedback architectures, the AD9621 offers performance not previously available in a monolithic operational amplifier.

***Protected by U.S. Patent 5,150,074 and others pending.**

Other members of the AD962X amplifier family are the AD9622 (G = +2), AD9623 (G = +4), and the AD9624 (G = +6). A separate data sheet is available from Analog Devices for each model. Each generic device has been designed for a different minimum stable gain setting, allowing users flexibility in optimizing system performance. Dynamic performance specifications such as slew rate, settling time, and distortion vary from model to model. The table below summarizes key performance attributes for the AD962X family and can be used as a selection guide.

The AD9621 is offered in industrial and military temperature ranges. Industrial versions are available in plastic DIP, SOIC, and cerdip; MIL versions are packaged in cerdips.

PRODUCT HIGHLIGHTS

1. Wide Large Signal Bandwidth
2. High Slew Rate
3. Fast Settling
4. Output Short-Circuit Protected

Parameter	AD9621	AD9622	AD9623	AD9624	Units
Minimum Stable Gain	+1	+2	+4	+6	V/V
Harmonic Distortion (20 MHz)	−52	−66	−64	−66	dB
Large Signal Bandwidth (4 V p-p)	130	160	190	200	MHz
SSBW (0.5 V p-p)	350	220	270	300	MHz
Slew Rate	1200	1500	2100	2200	V/μs
Rise/Fall Time (0.5 V Step)	2.4	1.7	1.6	1.5	ns

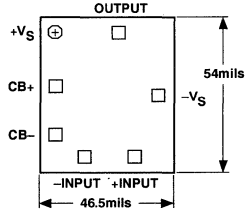
VI – All devices are 100% production tested at +25°C. 100% production tested at temperature extremes for extended temperature devices; sample tested at temperature extremes for commercial/industrial devices.



Chip Layout

THEORY OF OPERATION

The AD9621 is a wide bandwidth, unity gain stable voltage feedback amplifier. Since its open-loop frequency response follows the conventional 6 dB/octave roll-off, its gain bandwidth product is basically constant. Increasing its closed-loop gain results in a corresponding decrease in small signal bandwidth. The AD9621 typically maintains a 55 degree unity loop gain phase margin. This high margin minimizes the effects of signal and noise peaking.

Feedback Resistor Choice

At minimum stable gain (+1), the AD9621 provides optimum dynamic performance with $R_F \cong 51\ \Omega$. This resistor acts only as a parasitic suppressor against damped R_F oscillations that can occur due to lead (input, feedback) inductance and parasitic capacitance. For settling accuracy to 0.1% or less, this resistor should not be required if layout guidelines are closely followed. This value for R_F provides the best combination of wide bandwidth, low parasitic peaking, and fast settling time.

When the AD9621 is used in the transimpedance (I-to-V) mode, such as for photo-diode detection, the value for R_F and diode capacitance (C_I) are usually known. See Figure 1. Generally, the value of R_F selected will be in the kΩ range, and a shunt capacitor (C_F) across R_F will be required to maintain good amplifier stability. The value of C_F required to maintain <1 dB of peaking can be estimated as:

$$C_F \cong [(2\omega_o C_I R_F - 1)/\omega_O{}^2 R_F{}^2]^{1/2} \quad \Big| \quad R_F \geq 1k\Omega$$

where ω_O is equal to the unity gain bandwidth product of the amplifier in RAD/sec, and C_I is the equivalent total input capacitance at the inverting input. Typically ω_O is 700 × 10^6 RAD/sec (See Open Loop Frequency Response curve).

As an example, choosing R_F of 10 kΩ and C_I of 5 pF, requires C_F to be 1.1 pF (Note: C_I includes both the source and parasitic circuit capacitance). The bandwidth of the amplifier can be estimated using the C_F calculated as:

$$f_3\,dB \cong \frac{1.6}{2\,\pi\,R_F\,C_F}$$

For general voltage gain applications, the amplifier bandwidth can be estimated as:

$$f_3\,dB \cong \frac{\omega_O}{1 + \left(\frac{R_F}{R_G}\right)}$$

This estimation loses accuracy for gains approaching +2/−1 or lower due to the amplifier's damping factor. For these "low gain" cases, the bandwidth will actually extend beyond the calculated value. See Closed Loop BW plots.

As a rule of thumb, capacitor C_F will not be required if:

$$(R_F \| R_G)\,C_I \leq \frac{NG}{4\,\omega_O}$$

where NG is the Noise Gain ($1 + R_F/R_G$) of the circuit. For most voltage gain applications, this should be the case.

Wideband Voltage Feedback Amplifier

AD9622*

FEATURES
220 MHz Small Signal Bandwidth
160 MHz Large Signal BW (4 V p-p)
High Slew Rate: 1500 V/μs
Low Distortion: −66 dB @ 20 MHz
Fast Settling: 14 ns to 0.01%
3.5 nV/√Hz Spectral Noise Density
±3 V Supply Operation

APPLICATIONS
ADC Input Signal Amplifier
Differential Amplifiers
IF/RF Amplifiers
Pulse Amplifiers
Professional Video
DAC Current-to-Voltage
Baseband and Video Communications
Active Filters/Integrators/Log Amps

GENERAL DESCRIPTION

The AD9622 is one of a family of very high speed and wide bandwidth amplifiers utilizing a voltage feedback architecture. These amplifiers define a new level of performance for voltage feedback amplifiers, especially in the categories of large signal bandwidth, slew rate, settling, low distortion, and low noise.

Proprietary design architectures have resulted in an amplifier family that combines the most attractive attributes of both current feedback and voltage feedback amplifiers. The AD9622 exhibits extraordinarily accurate and fast pulse response characteristics (8 ns settling to 0.1%) as well as extremely wide small and large signal bandwidth previously found only in current feedback amplifiers. When combined with balanced high impedance inputs and low input noise more common to voltage feedback architectures, the AD9622 offers performance not previously available in a monolithic operational amplifier.

Other members of the AD962X amplifier family are the AD9621 (G = +1), AD9623 (G = +4), and the AD9624 (G = +6). A separate data sheet is available from Analog Devices for each model. Each generic device has been designed for a different minimum stable gain setting, allowing users flexibility in optimizing system performance. Dynamic performance specifications such as slew rate, settling time, and distortion vary from model to model. The table below summarizes key performance attributes for the AD962X family and can be used as a selection guide.

The AD9622 is offered in industrial and military temperature ranges. Industrial versions are available in plastic DIP, SOIC, and cerdip; MIL versions are packaged in cerdips.

PRODUCT HIGHLIGHTS

1. Wide Large Signal Bandwidth
2. High Slew Rate
3. Fast Settling
4. Low Distortion
5. Output Short-Circuit Protected
6. Low Intermodulation Distortion of High Frequencies

***Protected by U.S. Patent 5,150,074 and others pending.**

Chip Layout

THEORY OF OPERATION

The AD9622 is a wide bandwidth voltage feedback amplifier that is guaranteed for minimum gain stability of +2. Since its open loop frequency response follows the conventional 6 dB/octave roll-off, its gain bandwidth product is basically constant. Increasing its closed-loop gain results in a corresponding decrease in small signal bandwidth. The AD9622 typically maintains a 60 degree unity loop gain phase margin with $R_F \cong 270\ \Omega$. This high margin minimizes the effects of signal and noise peaking.

Feedback Resistor Choice

At minimum stable gain (+2), the AD9622 provides optimum dynamic performance with $R_F = 270\ \Omega$. When using this value and following the high speed layout guidelines, a shunt capacitor (C_F) should not be required. This value for R_F provides the best combination of wide bandwidth, low peaking, and distortion.

However, if improved gain flatness is desired, a shunt capacitor (C_F) will provide extra phase margin. This reduces both overshoot and peaking with only a slight reduction of bandwidth.

As an example, if the amplifier exhibits (worst case) peaking of 1 dB with $R_G \| R_F = 135\ \Omega$ ($A_V = 2$), then using a C_F of ≈ 1.5 pF across R_F will reduce this peaking to 0 dB. In addition, overshoot, noise, and settling time (0.01%) will also improve. This comes at the expense of slightly decreased closed-loop bandwidth due to the $R_F \times C_F$ time constant created.

If the equivalent input capacitance greatly exceeds 2 pF (due to source drive or long input traces to the amplifier), then added shunt capacitance (C_F) will be necessary to maintain stability.

Likewise, if larger R_G/R_F minimum-gain setting resistors are used, C_F will be necessary. As a rule of thumb, if the product of $R_F \| R_G \times C_I \leq 270 \times 10^{-12}$ seconds, then C_F is not required (for maximum bandwidth applications) and the amplifier's phase margin will maintain about 60°.

For $R_F \| R_G > 150\ \Omega$, use a C_F equal to $C_I \times R_G/R_F$. As the value of $R_F \| R_G$ increases, the bandwidth of the amplifier will begin to be controlled by the $R_F \times C_F$ time constant. Increasing C_F much beyond these guidelines will also cause amplifier instability.

Pulse Response

Unlike a traditional voltage feedback amplifier in which slew speed is usually dictated by its front end dc quiescent current and gain bandwidth product, the AD9622 provides "on demand" transconductance current that increases proportionally to the input "step" signal amplitude. This results in slew speeds (1500 V/μs) comparable to wideband current feedback designs. This, combined with relatively low input noise current (3.2 pA/$\sqrt{\text{Hz}}$), gives the AD9622 the best attributes of both voltage and current feedback amplifiers.

Bootstrap Capacitor (C_B)

In most applications, the C_B capacitor should not be required. Under certain conditions, it can be used to further enhance settling time performance.

Wideband Voltage Feedback Amplifier

AD9623*

FEATURES
270 MHz Small Signal Bandwidth
190 MHz Large Signal BW (4 V p-p)
High Slew Rate: 2100 V/μs
Low Distortion: −64 dB @ 20 MHz

Chip Layout

THEORY OF OPERATION

The AD9623 is a wide bandwidth voltage feedback amplifier that is guaranteed for minimum gain stability of +4. Since its open-loop frequency response follows the conventional 6 dB/octave roll-off, its gain bandwidth product is basically constant. Increasing its closed-loop gain results in a corresponding decrease in small signal bandwidth. The AD9623 typically maintains a 60 degree unity loop gain phase margin. This high margin minimizes the effects of signal and noise peaking.

Feedback Resistor Choice

At minimum stable gain (+4), the AD9623 provides optimum dynamic performance with $R_F \cong 390\ \Omega$. When using this value and following the high speed layout guidelines, a shunt capacitor (C_F) should not be required. This value R_F provides the best combination of wide bandwidth, low peaking, and distortion.

However, if improved gain flatness is desired, a shunt capacitor (C_F) will provide extra phase margin. This reduces both overshoot and peaking with only a slight reduction of bandwidth. See Figure 1.

As an example, if the amplifier exhibits (worst case) peaking of 1 dB with $R_G \| R_F = 98\ \Omega$ ($A_V = 4$), then using an effective C_F of ≈ 0.5–1 pF across R_F will reduce this peaking to 0 dB. In addition, overshoot, noise, and settling time (0.01%) will also improve. This comes at the expense of slightly decreased closed-loop bandwidth due to the $R_F \times C_F$ time constant created.

If total input capacitance greatly exceeds 3 pF (due to source drive or long input traces to the amplifier), then added shunt capacitance (C_F) will be necessary to maintain stability for minimum gain.

Likewise, if larger R_G/R_F minimum-gain setting resistors are used, C_F will be necessary. As a rule of thumb, if the product of $R_F \| R_G \times C_I \leq 300 \times 10^{-12}$ seconds, then C_F is not required (for maximum bandwidth at minimum gain) and the amplifier's phase margin will maintain about 60°.

For $R_F \| R_G > 150\ \Omega$, use a C_F equal to $C_I \times R_G/R_F$. For C_I (total) @ 2 pF, requires C_F to be 0.5 pF. This can be achieved by two 1 pF capacitors in series, or by using a resistor divider network at the amplifier's output in conjunction with a larger capacitor. Increasing C_F much beyond these guidelines will also cause amplifier instability.

Pulse Response

Unlike a traditional voltage feedback amplifier in which slew speed is usually dictated by its front end dc quiescent current and gain bandwidth product, the AD9623 provides "on demand" transconductance current that increases proportionally to the input "step" signal amplitude. This results in slew speeds (2100 V/μs) comparable to wideband current feedback designs. This, combined with relatively low input noise current (2.5 pA/$\sqrt{\text{Hz}}$), gives the AD9623 the best attributes of both voltage and current feedback amplifiers.

Bootstrap Capacitor (C_B)

In most applications, the C_B capacitor will not be required. Under certain conditions, it can be used to further enhance settling time performance.

9

Wideband Voltage Feedback Amplifier

AD9624*

FEATURES
300 MHz Small Signal Bandwidth
200 MHz Large Signal BW (4 V p-p)
High Slew Rate: 2200 V/μs
Low Distortion: −60 dB @ 20 MHz
Fast Settling: 15 ns to 0.01%
2.2 nV/√Hz Spectral Noise Density
±3 V Supply Operation

APPLICATIONS
ADC Input Driver
Differential Amplifiers
IF/RF Amplifiers
Pulse Amplifiers
Professional Video
DAC Current-to-Voltage
Baseband and Video Communications
Active Filters/Integrators/Log Amps

CONNECTION DIAGRAM

 # OPTIONALCAPACITOR CB CONNECTED HERE DECREASES SETTLING TIME (SEE TEXT).

GENERAL DESCRIPTION

The AD9624 is one of a family of very high speed and wide bandwidth amplifiers utilizing a voltage feedback architecture. These amplifiers define a new level of performance for voltage feedback amplifiers, especially in the categories of large signal bandwidth, slew rate, settling, low distortion, and low noise.

Proprietary design architectures have resulted in an amplifier family that combines the most attractive attributes of both current feedback and voltage feedback amplifiers. The AD9624 exhibits extraordinarily accurate and fast pulse response characteristics (8 ns settling to 0.1%) as well as extremely wide small and large signal bandwidth previously found only in current feedback amplifiers. When combined with balanced high impedance inputs and low input noise current more common to voltage feedback architectures, the AD9624 offers performance not previously available in a monolithic operational amplifier.

***Protected by U.S. Patent 5,150,074 and others pending.**

Other members of the AD962X amplifier family are the AD9621 (G = +1), AD9622 (G = +2), and the AD9623 (G = +4). A separate data sheet is available from Analog Devices for each model. Each generic device has been designed for a different minimum stable gain setting, allowing users flexibility in optimizing system performance. Dynamic performance specifications such as slew rate, settling time, and distortion vary from model to model. The table below summarizes key performance attributes for the AD962X family and can be used as a selection guide.

The AD9624 is offered in industrial and military temperature ranges. Industrial versions are available in plastic DIP, SOIC, and cerdip; MIL versions are packaged in cerdips.

PRODUCT HIGHLIGHTS

1. Wide Large Signal Bandwidth
2. High Slew Rate
3. Fast Settling
4. Low Distortion
5. Output Short-Circuit Protected
6. Low Intermodulation Distortion at High Frequencies

Parameter	AD9621	AD9622	AD9623	AD9624	Units
Minimum Stable Gain	+1	+2	+4	+6	V/V
Harmonic Distortion (20 MHz)	−52	−66	−64	−66	dB
Large Signal Bandwidth (4 V p-p)	130	160	190	200	MHz

Chip Layout

THEORY OF OPERATION

The AD9624 is a wide bandwidth voltage feedback amplifier that is guaranteed for minimum gain stability of +6. Since its open loop frequency response follows the conventional 6 dB/octave roll-off, its gain bandwidth product is basically constant. Increasing its closed-loop gain results in a corresponding decrease in small signal bandwidth. The AD9624 typically maintains a 60 degree unity loop gain phase margin with $R_F \cong 510\ \Omega$. This high margin minimizes the effects of signal and noise peaking.

Feedback Resistor Choice

At minimum stable gain (+6), the AD9624 provides optimum dynamic performance with $R_F = 510\ \Omega$. When using this value and following the high speed layout guidelines, a shunt capacitor (C_F) should not be required. This value for R_F provides the best combination of wide bandwidth, low peaking, and distortion.

However, if improved gain flatness is desired, a shunt capacitor (C_F) will provide extra phase margin. This reduces both overshoot and peaking with only a slight reduction of bandwidth.

As an example, if the amplifier exhibits (worst case) peaking of 1.2 dB with $R_G \| R_F = 85\ \Omega$ ($A_V = 6$), then using a C_F of ≈ 0.5 pF (two 1 pF capacitors in series) across R_F will reduce this peaking to 0 dB. In addition, overshoot, noise, and settling time (<0.01%) will also improve. This comes at the expense of slightly decreased closed-loop bandwidth due to the $R_F \times C_F$ time constant created.

If the equivalent input capacitance greatly exceeds 4 pF (due to source drive or long input traces to the amplifier), then added shunt capacitance (C_F) will be necessary to maintain stability at minimum gain.

As a rule of thumb, if the product of $R_F \| R_G \times C_I \leq 300 \times 10^{-12}$ seconds, then C_F is not required (for maximum bandwidth applications) and the amplifier's phase margin will maintain about 60°. Generally, this should be the case.

Pulse Response

Unlike a traditional voltage feedback amplifier in which slew speed is usually dictated by its front end dc quiescent current and gain bandwidth product, the AD9624 provides "on demand" transconductance current that increases proportionally to the input "step" signal amplitude. This results in slew speeds (2000 V/μs) comparable to wideband current feedback designs. This, combined with relatively low input noise current (2.5 pA/$\sqrt{\text{Hz}}$), gives the AD9624 the best attributes of both voltage and current feedback amplifiers.

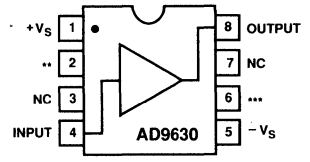
Low Distortion, 750 MHz Closed-Loop Buffer Amp

AD9630*

FEATURES
Excellent Gain Accuracy: 0.99 V/V
Wide Bandwidth: 750 MHz
Slew Rate: 1200 V/μs
Low Distortion
−65 dBc @ 20 MHz
−80 dBc @ 4.3 MHz
Settling Time
6 ns to 0.1%
8 ns to 0.02%
Low Noise: 2.4 nV/√Hz
Improved Source for CLC-110

APPLICATIONS
IF/Communications
Impedance Transformations
Drives Flash ADCs
Line Driving

PIN CONFIGURATION



**OPTIONAL +VS ***OPTIONAL −VS
NC = NO CONNECT

NOTE: FOR BEST SETTLING TIME PERFORMANCE USE OPTIONAL POWER SUPPLIES. ALL SPECIFICATIONS ARE BASED ON USING SINGLE ±VS CONNECTIONS EXCEPT FOR SETTLING TIME TO 0.02% AND SMALL SIGNAL S21. CONSULT THE FACTORY FOR VERSIONS WITH OPTIONAL POWER SUPPLY PINS DISCONNECTED INTERNAL TO THE PACKAGE.

9

General Description

The AD9630 is a monolithic buffer amplifier that utilizes innovative (patent pending) closed-loop design techniques to achieve exceptional gain accuracy, wide bandwidth, and low distortion. Slew rate limiting has been overcome as indicated by the 1200 V/μs slew rate; this improvement allows the user greater flexibility in wideband and pulse applications. The second harmonic distortion terms for an analog input tone of 4.3 MHz and 20 MHz are −80 dBc and −66 dBc, respectively. Clearly, the AD9630 establishes a new standard by combining in one part outstanding dc and dynamic performance.

The large signal bandwidth, low distortion over frequency, and drive capabilities of the AD9630 make the buffer an ideal flash ADC driver. The AD9630 provides better signal fidelity than many of the flash ADCs that it has been designed to drive.

Other applications which require increased current drive at unity voltage gain such as cable driving benefit from the AD9630's performance.

The AD9630 is available in Plastic DIP (N), Ceramic DIP (Q), and SOIC (R). Consult with the factory concerning availability of MIL-STD-883 parts. Die are dc tested at +25°C.

NOTES
[1]Absolute maximum ratings are limiting values to be applied individually, and beyond which the serviceability of the circuit may be impaired. Functional operability is not necessarily implied. Exposure to absolute maximum rating conditions for an extended period of time may affect device reliability.
[2]Output is short-circuit protected to ground, but not to supplies. Prolonged short circuit to ground may affect device reliability.
[3]Typical thermal impedances (part soldered onto board): Mini-DIP (N): θ_{JA} = 110°C/W; θ_{JC} = 30°C/W; SOIC (R): θ_{JA} = 150°C/W; θ_{JC} = 50°C/W; Cerdip (Q): θ_{JA} = 110°C/W; θ_{JC} = 20°C/W.
[4]Short-term settling with 50 Ω source impedance.

EXPLANATION OF TEST LEVELS

Test Level
- I 100% Production tested.
- II 100% Production tested at +25°C and sample tested at specified temperatures. AC testing of AN and AR grades done on sample basis only.
- III Sample tested only.
- IV Parameter is guaranteed by design and characterization testing.
- V Typical value.
- VI S versions are 100% production tested at temperature extremes. Other grades are sample tested at extremes.

AD9630 Burn-In Circuit

THEORY OF OPERATION

The AD9630 is a wide-bandwidth, closed-loop, unity-gain buffer which makes use of a new voltage-feedback architecture (Patent Pending). This architecture brings together wide bandwidth and high slew rate along with exceptional dc linearity. Most previous wide bandwidth buffers achieved their bandwidth by utilizing an open-loop topology which sacrificed both dc linearity and frequency distortion when driven into low load impedances. The design's high loop correction factor radically improves dc linearity and distortion characteristics without diminishing bandwidth. This, in combination with high slew rate, results in exceptionally low distortion over a wide frequency range.

The AD9630 is an excellent choice to drive high speed and high resolution analog-to-digital Converters. Its output stage is designed to drive high speed flash converters with minimal or no series resistance. A current booster built into the output driver helps to maintain low distortion.

Parasitic or load capacitance (>7 pF) connected directly to the AD9630 output will result in frequency peaking. A small series resistor (R_S) connected between the buffer output and capacitive load will negate this effect. Figure 1 shows the optimal value of R_S as a function of C_L to obtain the flattest frequency response. Figure 2 illustrates frequency response for various capacitive loads utilizing the recommended R_S.

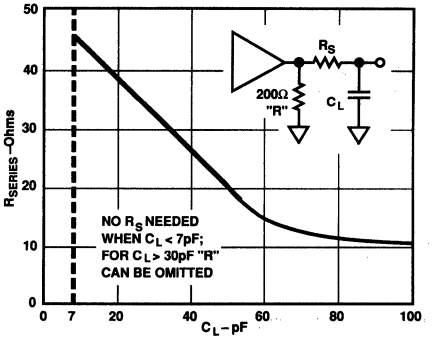

Figure 1. Recommended R_S vs. C_L

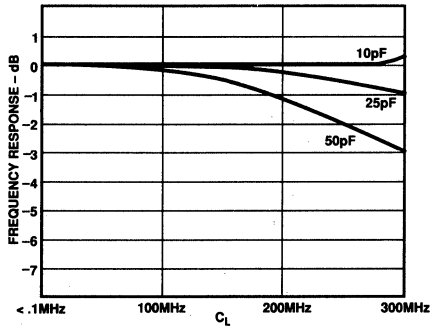

Figure 2. Frequency Response vs. C_L with Recommended R_S

In pulse mode applications, with R_S equal to approximately 12 ohms, capacitive loads of up to 50 pF can be driven with minimal settling time degradation.

Ultralow Distortion, Wide Bandwidth Voltage Feedback Op Amps

AD9631/AD9632

FEATURES

Wide Bandwidth — AD9631, G = +1 / AD9632, G = +2
- **Small Signal** — 320 MHz / 250 MHz
- **Large Signal (4 V p-p)** — 175 MHz / 180 MHz

Ultralow Distortion (SFDR), Low Noise
- **–113 dBc typ @ 1 MHz**
- **–95 dBc typ @ 5 MHz**
- **–72 dBc typ @ 20 MHz**
- **+46 dBc 3rd Order Intercept @ 25 MHz**
- **7.0 nV/$\sqrt{Hz}$ Spectral Noise Density**

High Speed
- **Slew Rate 1300 V/μs**
- **Settling 16 ns to 0.01%, 2 V Step**

±3 V to ±5 V Supply Operation

17 mA Supply Current

APPLICATIONS

ADC Input Driver
Differential Amplifiers
IF/RF Amplifiers
Pulse Amplifiers
Professional Video
DAC Current to Voltage
Baseband and Video Communications
Pin Diode Receivers
Active Filters/Integrators/Log Amps

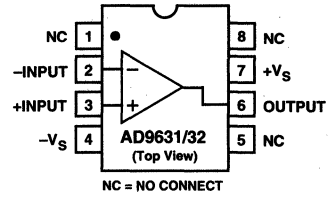
8-Pin Plastic Mini-DIP (N), Cerdip (Q), and SO (R) Packages



PRODUCT DESCRIPTION

The AD9631 and AD9632 are very high speed and wide bandwidth amplifiers. They are an improved performance alternative to the AD9621 and AD9622. The AD9631 is unity gain stable. The AD9632 is stable at gains of two or greater. Utilizing a voltage feedback architecture, the AD9631/AD9632's exceptional settling time, bandwidth, and low distortion meet the requirements of many applications which previously depended on current feedback amplifiers. Its classical op amp structure works much more predictably in many designs.

A proprietary design architecture has produced an amplifier that combines many of the best characteristics of both current feedback and voltage feedback amplifiers. The AD9631 and AD9632 exhibit exceptionally fast and accurate pulse response (16 ns to 0.01%) as well as extremely wide small signal and large signal bandwidth and ultralow distortion. The AD9631 achieves –72 dBc at 20 MHz with 320 MHz small signal and 175 MHz large signal bandwidths.

These characteristics position the AD9631/AD9632 ideally for driving flash as well as high resolution ADCs. Additionally, the balanced high impedance inputs of the voltage feedback architecture allow maximum flexibility when designing active filters.

The AD9631 is offered in industrial (–40°C to +85°C) and military (–55°C to +125°C) temperature ranges and the AD9632 in industrial. Industrial versions are available in plastic DIP and SOIC; MIL versions are packaged in cerdip.

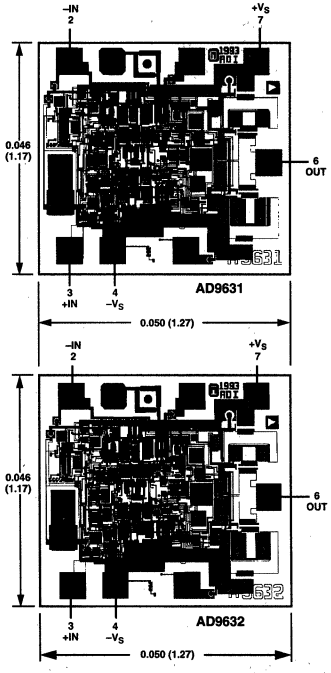
Dimensions shown in inches and (mm).



MAXIMUM POWER DISSIPATION

The maximum power that can be safely dissipated by these devices is limited by the associated rise in junction temperature. The maximum safe junction temperature for plastic encapsulated devices is determined by the glass transition temperature of the plastic, approximately +150°C. Exceeding this limit temporarily may cause a shift in parametric performance due to a change in the stresses exerted on the die by the package. Exceeding a junction temperature of +175°C for an extended period can result in device failure.

While the AD9631 and AD9632 are internally short circuit protected, this may not be sufficient to guarantee that the maximum junction temperature (+150°C) is not exceeded under all conditions. To ensure proper operation, it is necessary to observe the maximum power derating curves.

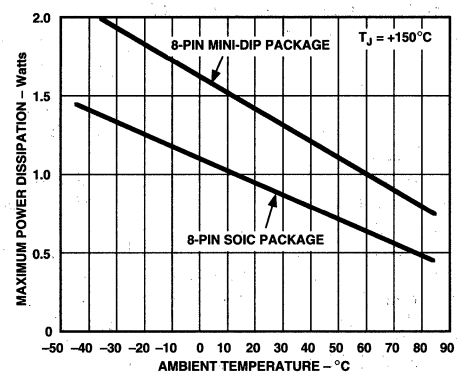


Figure 2. Plot of Maximum Power Dissipation vs. Temperature

AD9632-EB		Evaluation Board	

*N = Plastic DIP; Q = Cerdip; R= SOIC (Small Outline Integrated Circuit). For outline information see Package Information section.

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although these devices feature proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

THEORY OF OPERATION

General

The AD9631 and AD9632 are wide bandwidth, voltage feedback amplifiers. Since their open-loop frequency response follows the conventional 6 dB/octave roll-off, their gain bandwidth product is basically constant. Increasing their closed-loop gain results in a corresponding decrease in small signal bandwidth. This can be observed by noting the bandwidth specification between the AD9631 (gain of 1) and AD9632 (gain of 2). The AD9631/AD9632 typically maintain 65 degrees of phase margin. This high margin minimizes the effects of signal and noise peaking.

Feedback Resistor Choice

The value of the feedback resistor is critical for optimum performance on the AD9631 (gain +1) and less critical as the gain increases. Therefore, this section is specifically targeted at the AD9631.

At minimum stable gain (+1), the AD9631 provides optimum dynamic performance with R_F = 140 Ω. This resistor acts only as a parasitic suppressor against damped RF oscillations that can occur due to lead (input, feedback) inductance and parasitic capacitance. This value of R_F provides the best combination of wide bandwidth, low parasitic peaking, and fast settling time.

In fact, for the same reasons, a 100–130 Ω resistor should be placed in series with the positive input for other AD9631 noninverting and all AD9631 inverting configurations. The correct connection is shown in Figures 57 and 58.

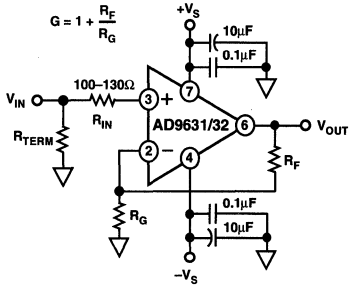

Figure 57. Noninverting Operation

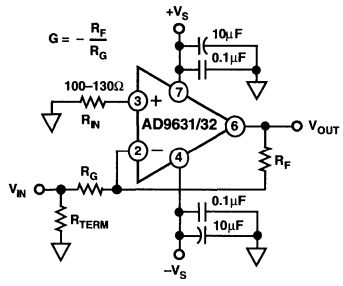

Figure 58. Inverting Operation

When the AD9631 is used in the transimpedance (I to V) mode, such as in photodiode detection, the value of R_F and diode capacitance (C_I) are usually known. Generally, the value of R_F selected will be in the kΩ range, and a shunt capacitor (C_F) across R_F will be required to maintain good amplifier stability. The value of C_F required to maintain optimal flatness (<1 dB Peaking) and settling time can be estimated as:

$$C_F \cong \left[(2\,\omega_O C_I R_F - 1)/\omega_O{}^2\, R_F{}^2\right]^{1/2}$$

where ω_O is equal to the unity gain bandwidth product of the amplifier in rad/sec, and C_I is the equivalent total input capacitance at the inverting input. Typically $\omega_O = 800 \times 10^6$ rad/sec (see Open-Loop Frequency Response curve (Figure 17).

As an example, choosing R_F = 10 kΩ and C_I = 5 pF, requires C_F to be 1.1 pF (Note: C_I includes both source and parasitic circuit capacitance). The bandwidth of the amplifier can be estimated using the C_F calculated as:

$$f_{3\,dB} \cong \frac{1.6}{2\pi R_F C_F}$$

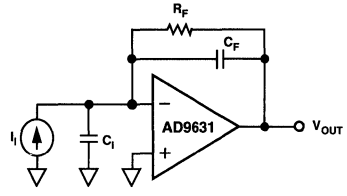

Figure 59. Transimpedance Configuration

For general voltage gain applications, the amplifier bandwidth can be closely estimated as:

$$f_{3\,dB} \cong \frac{\omega_O}{2\pi\left[1+\left(\frac{R_F}{R_G}\right)\right]}$$

This estimation loses accuracy for gains of +2/–1 or lower due to the amplifier's damping factor. For these "low gain" cases, the bandwidth will actually extend beyond the calculated value (see Closed-Loop BW plots, Figures 15 and 27).

As a rule of thumb, capacitor C_F will not be required if:

$$(R_F \| R_G) \times C_I \leq \frac{NG}{4\,\omega_O}$$

where *NG* is the Noise Gain ($1 + R_F/R_G$) of the circuit. For most voltage gain applications, this should be the case.

Pulse Response

Unlike a traditional voltage feedback amplifier, where the slew speed is dictated by its front end dc quiescent current and gain bandwidth product, the AD9631 and AD9632 provide "on demand" current that increases proportionally to the input "step" signal amplitude. This results in slew rates (1300 V/µs) comparable to wideband current feedback designs. This, combined with relatively low input noise current (2.0 pA/$\sqrt{\text{Hz}}$), gives the AD9631 and AD9632 the best attributes of both voltage and current feedback amplifiers.

Large Signal Performance

The outstanding large signal operation of the AD9631 and AD9632 is due to a unique, proprietary design architecture. In order to maintain this level of performance, the maximum 550 V-MHz product must be observed, (e.g., @ 100 MHz, $V_O \leq 5.5$ V p-p).

Power Supply Bypassing

Adequate power supply bypassing can be critical when optimizing the performance of a high frequency circuit. Inductance in the power supply leads can form resonant circuits that produce peaking in the amplifier's response. In addition, if large current transients must be delivered to the load, then bypass capacitors (typically greater than 1 µF) will be required to provide the best settling time and lowest distortion. A parallel combination of at least 4.7 µF, and between 0.1 µF and 0.01 µF, is recommended. Some brands of electrolytic capacitors will require a small series damping resistor ≈4.7 Ω for optimum results.

Driving Capacitive Loads

The AD9631 and AD9632 were designed primarily to drive nonreactive loads. If driving loads with a capacitive component is desired, the best frequency response is obtained by the addition of a small series resistance as shown in Figure 60. The accompanying graph shows the optimum value for R_{SERIES} vs. capacitive load. It is worth noting that the frequency response of the circuit when driving large capacitive loads will be dominated by the passive roll-off of R_{SERIES} and C_L.

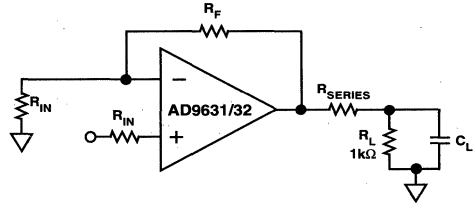

Figure 60. Driving Capacitive Loads

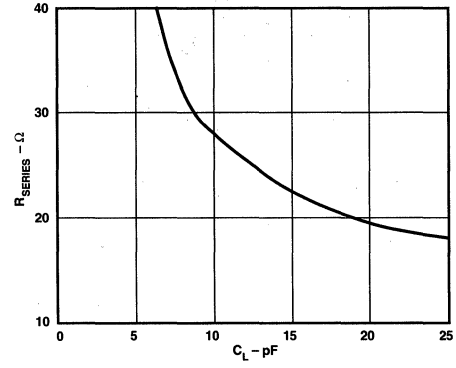

Figure 61. Recommended R_{SERIES} vs. Capacitive Load

Improved Second Source to the EL2020

ADEL2020

FEATURES

Ideal for Video Applications
- 0.02% Differential Gain
- 0.04° Differential Phase
- 0.1 dB Bandwidth to 25 MHz (G = +2)

High Speed
- 90 MHz Bandwidth (−3 dB)
- 500 V/μs Slew Rate
- 60 ns Settling Time to 0.1% (V_O = 10 V Step)

Low Noise
- 2.9 nV/√Hz Input Voltage Noise

Low Power
- 6.8 mA Supply Current
- 2.1 mA Supply Current (Power-Down Mode)

High Performance Disable Function
- Turn-Off Time of 100 ns
- Input to Output Isolation of 54 dB (Off State)

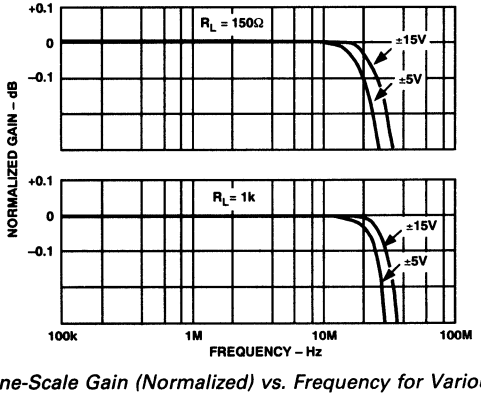
PRODUCT DESCRIPTION

The ADEL2020 is an improved second source to the EL2020. This op amp improves on all the key dynamic specifications while offering lower power and lower cost. The ADEL2020 offers 50% more bandwidth and gain flatness of 0.1 dB to beyond 25 MHz. In addition, differential gain and phase are less than 0.05% and 0.05° while driving one back terminated cable (150 Ω).

The ADEL2020 offers other significant improvements. The most important of these is lower power supply current, 33% less than the competition while offering higher output drive. Important specs like voltage noise and offset voltage are less than half of those for the EL2020.

The ADEL2020 also features an improved disable feature. The disable time (to high output impedance) is 100 ns with guaranteed break before make. Finally the ADEL2020 is offered in the industrial temperature range of −40°C to +85°C in both plastic DIP and SOIC package.



Fine-Scale Gain (Normalized) vs. Frequency for Various Supply Voltages. R_F = 750 Ω, Gain = +2

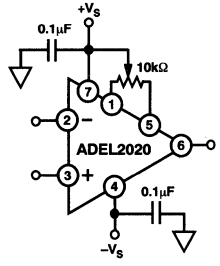
20-Pin SOIC Package: θ_{JA} = 150°C/Watt

ESD SUSCEPTIBILITY

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 volts, which readily accumulate on the human body and on test equipment, can discharge without detection. Although the ADEL2020 features ESD protection circuitry, permanent damage may still occur on these devices if they are subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid any performance degradation or loss of functionality.

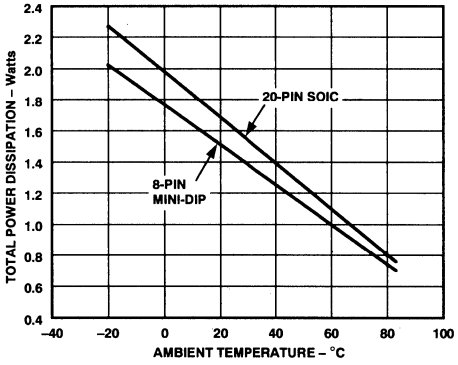


Offset Null Configuration

MAXIMUM POWER DISSIPATION

The maximum power that can be safely dissipated by the ADEL2020 is limited by the associated rise in junction temperature. For the plastic packages, the maximum safe junction temperature is 145°C. If the maximum is exceeded momentarily, proper circuit operation will be restored as soon as the die temperature is reduced. Leaving the device in the "overheated" condition for an extended period can result in device burnout. To ensure proper operation, it is important to observe the derating curves below.

While the ADEL2020 is internally short circuit protected, this may not be sufficient to guarantee that the maximum junction temperature is not exceeded under all conditions.



Maximum Power Dissipation vs. Temperature

GENERAL DESIGN CONSIDERATIONS

The ADEL2020 is a current feedback amplifier optimized for use in high performance video and data acquisition systems. Since it uses a current feedback architecture, its closed-loop bandwidth depends on the value of the feedback resistor. The −3 dB bandwidth is also somewhat dependent on the power supply voltage. Lowering the supplies increases the values of internal capacitances, reducing the bandwidth. To compensate for this, smaller values of feedback resistor are used at lower supply voltages.

POWER SUPPLY BYPASSING

Adequate power supply bypassing can be critical when optimizing the performance of a high frequency circuit. Inductance in the power supply leads can contribute to resonant circuits that produce peaking in the amplifier's response. In addition, if large current transients must be delivered to the load, then bypass capacitors (typically greater than 1 μF) will be required to provide the best settling time and lowest distortion. Although the recommended 0.1 μF power supply bypass capacitors will be sufficient in most applications, more elaborate bypassing (such as using two paralleled capacitors) may be required in some cases.

CAPACITIVE LOADS

When used with the appropriate feedback resistor, the ADEL2020 can drive capacitive loads exceeding 1000 pF directly without oscillation. Another method of compensating for large load capacitance is to insert a resistor in series with the loop output. In most cases, less than 50 Ω is all that is needed to achieve an extremely flat gain response.

OFFSET NULLING

A 10 kΩ pot connected between Pins 1 and 5, with its wiper connected to V+, can be used to trim out the inverting input current (with about ±20 μA of range). For closed-loop gains above about 5, this may not be sufficient to trim the output offset voltage to zero. Tie the pot's wiper to ground through a large value resistor (50 kΩ for ±5 V supplies, 150 kΩ for ±15 V supplies) to trim the output to zero at high closed-loop gains.

OPERATION AS A VIDEO LINE DRIVER

The ADEL2020 is designed to offer outstanding performance at closed-loop gains of one or greater. At a gain of 2, the ADEL2020 makes an excellent video line driver. The low differential gain and phase errors and wide −0.1 dB bandwidth are nearly independent of supply voltage and load. For applications requiring widest 0.1 dB bandwidth, it is recommended to use 715 Ω feedback and gain resistors. This will result in about 0.05 dB of peaking and a −0.1 dB bandwidth of 30 MHz on ±15 V supplies.

DISABLE MODE

By pulling the voltage on Pin 8 to common (0 V), the ADEL2020 can be put into a disabled state. In this condition, the supply current drops to less than 2.8 mA, the output becomes a high impedance, and there is a high level of isolation from input to output. In the case of a line driver for example, the output impedance will be about the same as for a 1.5 kΩ resistor (the feedback plus gain resistors) in parallel with a 13 pF capacitor (due to the output) and the input to output isolation will be better than 50 dB at 10 MHz.

Leaving the disable pin disconnected (floating) will leave the part in the enabled state.

In cases where the amplifier is driving a high impedance load, the input to output isolation will decrease significantly if the input signal is greater than about 1.2 V peak to peak. The isolation can be restored to the 50 dB level by adding a dummy load (say 150 Ω) at the amplifier output. This will attenuate the feedthrough signal. (This is not an issue for multiplexer applications where the outputs of multiple ADEL2020s are tied together as long as at least one channel is in the ON state.) The input impedance of the disable pin is about 35 kΩ in parallel with a few pF. When grounded, about 50 μA flows out of the disable pin for ±5 V supplies.

Break before make operation is guaranteed by design. If driven by standard CMOS logic, the disable time (until the output is high impedance), is about 100 ns and the enable time (to low impedance output) is about 160 ns. Since it has an internal pull-up resistor of about 35 kΩ, the ADEL2020 can be used with open drain logic as well. In this case, the enable time is increased to about 1 μs.

If there is a nonzero voltage present on the amplifier's output at the time it is switched to the disabled state, some additional decay time will be required for the output voltage to relax to zero. The total time for the output to go to zero will generally be about 250 ns and is somewhat dependent on the load impedance.

ANALOG DEVICES

Closed-Loop High Speed Buffer

BUF04*

FEATURES
Bandwidth – 110 MHz
Slew Rate – 3000 V/μs
Low Offset Voltage – < 1 mV
Very Low Noise – < 4 nV/√Hz
Low Supply Current – 8.5 mA Mux
Wide Supply Range – ±5 to ±15 V
Drives Capacitive Loads
Pin Compatible with BUF03

APPLICATIONS
Instrumentation Buffer
RF Buffer
Line Driver
High Speed Current Source
Op Amp Output Current Booster
High Performance Audio
High Speed AD/DA

GENERAL DESCRIPTION

The BUF04 is a wideband, closed-loop buffer that combines state of the art dynamic performance with excellent dc performance. This combination enables designers to maximize system performance without any speed versus dc accuracy compromises.

Built on a high speed Complementary Bipolar (CB) process for better power performance ratio, the BUF04 consumes less than 8.5 mA operating from ±5 V or ±15 V supplies. With a 2000 V/μs min slew rate, and 100 MHz gain bandwidth product, the BUF04 is ideally suited for use in high speed applications where low power dissipation is critical.

Full ±10 V output swing over the extended temperature range along with outstanding ac performance and high loop gain accuracy makes the device useful in high speed data acquisition systems.

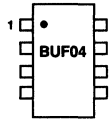
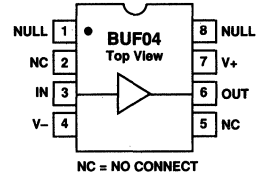
(S Suffix)



Plastic DIP
8-Lead and Cerdip
(P, Z Suffix)



High slew rate and very low noise and THD, coupled with wide input and output dynamic range, make the BUF04 an excellent choice for video and high performance audio circuits.

The BUF04's inherent ability to drive capacitive loads over a wide voltage and temperature range makes it extremely useful for a wide variety of applications in military, industrial, and commercial equipment.

The BUF04 is specified over the extended industrial (−40°C to +85°C) and military (−55°C to +125°C) temperature range. BUF04s are available in plastic and ceramic DIP plus SO-8 surface mount packages.

FUNCTIONAL DESCRIPTION

The BUF04 is a closed-loop voltage buffer based on a current-feedback architecture. Its high open-loop transimpedance, high output current drive capability, and its low input offset voltage makes it useful in a variety of applications, such as buffering the inputs of sampling and flash A/D converters, audio and video line drivers, active filters, and precision op amp boosters.

A transistor-level equivalent circuit for the BUF04 is illustrated in Figure 29. The input stage consists of a pair of emitter-follower transistors, Q1 and Q2, whose outputs drive a second set of transistors, Q3 and Q4. The emitters of Q3 and Q4 are connected together through diodes, D1 and D2, to form a low-impedance input for the feedback signal (in current mode) from the output stage. The outputs of Q3 and Q4 are then "mirrored" to Q5 and Q6 which form the gain stage of the BUF04. The signal is taken from the collectors of Q5 and Q6 which drive a "Darlington-connected" output stage made up of transistors Q7–Q10. Three R-C networks (R1-C1, R2-C2, and R3-C3) form feed-forward paths which bypass certain sections of the BUF04 for improved high frequency performance and capacitive load drive capability. Since the signal conveyed internally in the BUF04 is a current, the frequency response and slew rate of the BUF04 are insensitive to supply voltage variations.

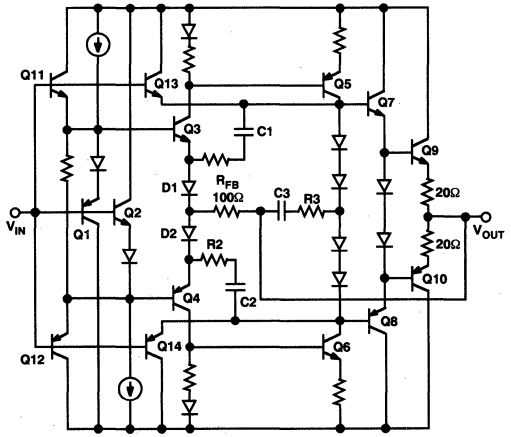

Figure 29. Transistor-Level Equivalent Circuit

An interesting feature of the BUF04 architecture is the use of "slew-enhancement" transistors, Q11–Q14. Under normal small-signal (V_{IN} < 2 V_{be}s) conditions, these transistors are normally "OFF." In large signals, high speed transient applications where the input signal is > 2 V_{be}s, these transistors turn on and literally "brute-force" the output to follow the input. When the input signal drops below 2 V_{be}s, the transistors return to their normally "OFF" state.

A two-terminal equivalent circuit of the BUF04 is shown in Figure 30 where the transistor-level equivalent circuit is reduced to its essential elements. The input stage develops a signal current, I_{IN}, that is replicated by an internal current conveyor so as to flow through R_t, the transimpedance of the BUF04. The voltage developed across R_t is buffered by a unity-gain output voltage follower. With an open-loop R_t of 400 kΩ and an R_{IN} of 30 Ω, the voltage gain of the BUF04, given by the ratio R_t/R_{IN} is approximately 13,000—accurate to approximately 13.5 bits. The BUF04's open-loop ac transimpedance response is determined by the open-loop pole formed by R_t and C_t. Since C_t is typically 8 pF, the open-loop pole occurs at approximately 50 kHz.

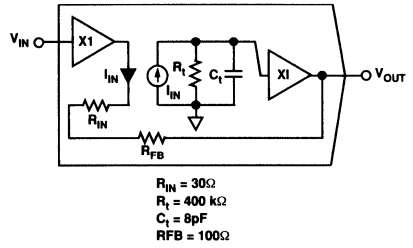

Figure 30. Current-Feedback Functional Equivalent Circuit of the BUF04

Grounding and Bypassing Considerations

To take full advantage of the BUF04's very wide bandwidth, high slew rates, and dynamic range capabilities requires due diligence with regard to supply bypassing. In high speed circuits, the supply bypassing network must provide a very low-impedance return path for currents flowing to and from the load network. As with any high speed application, multiple bypassing is always recommended. A 10 μF tantalum electrolytic in parallel with a 0.1 μF ceramic capacitor is sufficient for most applications. For those high speed applications where output load currents approach 50 mA, small-valued resistors (1.1 Ω to 4.7 Ω) in series with the tantalum capacitors may improve circuit transient response by damping out the capacitor's self-inductance. Figure 31 illustrates bypassing recommendations.

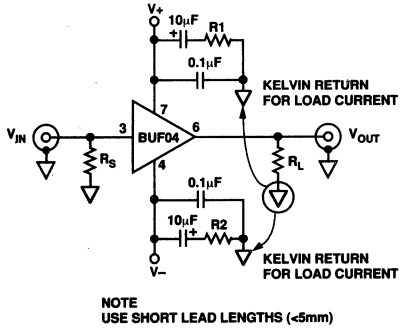

Figure 31. Recommended Power-Supply Bypassing

To minimize the effects of high-frequency coupling, circuits must be built with short interconnect leads, and large ground planes should be used whenever possible to provide a low resistance, low-inductance circuit path. Sockets should be avoided because the increased interlead capacitance can degrade bandwidth and stability. If sockets are necessary, individual pin sockets (oftentimes called "cage jacks," AMP Part No. 5-330808-3 or 5-330808-6) should be used. They contribute far less stray reactance than molded socket assemblies.

Offset Voltage Nulling

Although the offset voltage of the BUF04 is very low (1 mV, maximum) for such a high speed buffer, the circuit shown in Figure 32 can be used if additional offset voltage nulling is required. A potentiometer ranging from 1k to 10k can be used for V_{OS} nulling; with a 10 kΩ potentiometer, the trim range is ±30 mV.

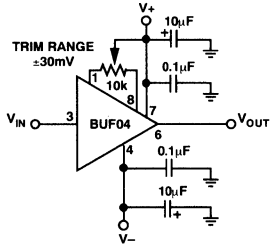

Figure 32. Optional Offset Voltage Nulling Scheme

APPLICATIONS

Output Short-Circuit Protection

To optimize the transient response and output voltage swing of the BUF04, internal output short-circuit current limiting was omitted. Although the BUF04 can provide continuous output currents of 50 mA without protection, direct connection of the BUF04's output to ground or to the supplies will destroy the device. An active current limit technique, illustrated in Figure 33, provides the necessary short-circuit protection while retaining full dc output voltage swing to the load.

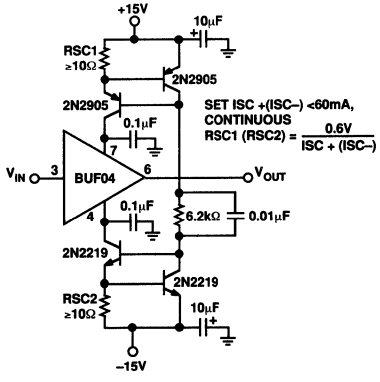

Figure 33. Short-Circuit Current Limiting Using Current Sources

Output Current Transient Recovery

Settling characteristics of high speed buffers also include the buffer's ability to recover, i.e., settle, from a transient output current load condition. When driving the input of an A/D converter, especially the successive-approximation converter types, the buffer must maintain a constant output voltage under dynamically changing load current conditions. In these types of converters, the comparison point is usually diode-clamped, but it may deviate several hundred millivolts resulting in high frequency modulation of the A/D input current. Open-loop and closed-loop buffers (also, op amps configured as followers) that exhibit high closed-loop output impedances and/or low unity-gain crossover frequencies recover very slowly from output load current transients. This slow recovery leads to linearity errors or missing codes because of errors in the instantaneous input voltage. Therefore, the buffer (or op amp) chosen for this type of application should exhibit low output impedance and high unity-gain bandwidth so that its output has had a chance to settle to its nominal value before the converter makes its comparison.

The circuit in Figure 34 illustrates a settling measurement circuit for evaluating the recovery time of high speed buffers from an output load current transient. The input to the buffer is grounded for ease of measuring the recovery time, and two resistors are used to sum steady-state and transient load currents at the output. As a worst-case condition, R1, was chosen such that the BUF04 would source (or sink) a steady-state current of 25 mA. R2 was then chosen to add a 10 mA transient current upon the steady-state value. To set accurately the nodal voltages internal to the BUF04, the supply voltages were offset by the voltage applied to R1. Because of its high transimpedance, wide bandwidth, and low output impedance, the BUF04 exhibits an extremely fast recovery time of 60 ns to 0.01%, as shown in Figure 34. Results were identical regardless whether the BUF04 was sourcing or sinking current.

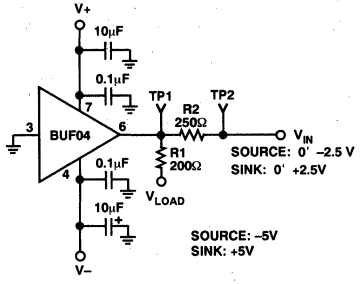

Figure 34. Transient Output Load Current Test Circuit

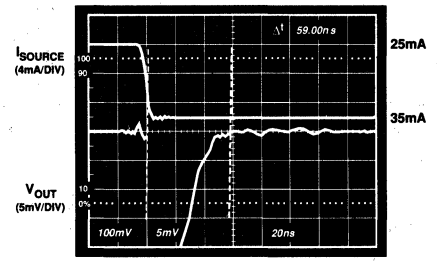

Figure 35. BUF04's Output Load Current Recovery Time

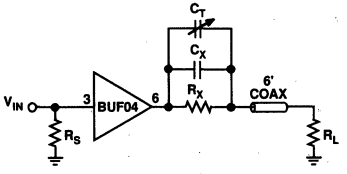
Terminated Line Drivers

The BUF04's high output current, large slew rate, and wide bandwidth all combine to make it an ideal device for high speed line driver applications. As shown in Figure 36, the BUF04 can be configured for driving doubly terminated 50 Ω and 75 Ω cables. To optimize the circuit's pulse response, a capacitor, C_T (C_X + C_{TRIM}), is connected across the series back termination. The BUF04 can drive a 50 Ω line to ±2.5 V and a 75 Ω line to ±3.75 V when operating on ±15 V supplies.



Z_O	COAX	R_S, R_L	R_X	C_X	C_T

75Ω	RG-59	75Ω	75	62pF	3–15pF

Figure 36. Line Driver Configuration

Low-Pass Active Filter

In many signal-conditioning applications, filters are required to band-limit noise or altogether eliminate other unwanted signals prior to conversion. Often, high frequency filters are needed for these applications; however, there are few op amps that exhibit the high open-loop gain and wide unity-gain crossover frequency required for these applications. As illustrated in Figure 37, the BUF04 and a handful of passive components can be configured as a high frequency, low-pass active filter. Since the filter configuration is a unity-gain Sallen-Key topology, the BUF04 is particularly well suited for this application. In this circuit, an additional resistor, R3, was added to prevent interaction between C2 and the BUF04's input capacitance.

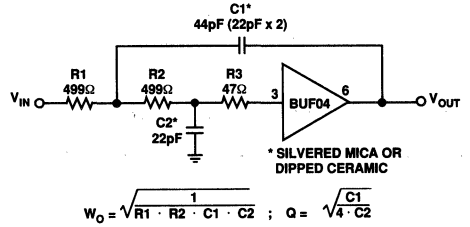

Figure 37. A 10 MHz Low-Pass Active Filter

Operation Within an Op Amp Feedback Loop

The BUF04 is well suited as a current booster or isolation buffer within the closed loop of precision op amps such as the OP177, the OP97, the OP27, or the OP77. Since the BUF04 is a closed-loop voltage buffer, no interstage coupling resistor between the op amp and the buffer's input is required for circuit stability. The wide bandwidth and high slew rate of the BUF04 assure that the loop has the characteristics of the op amp; hence, no additional rolloff is required.

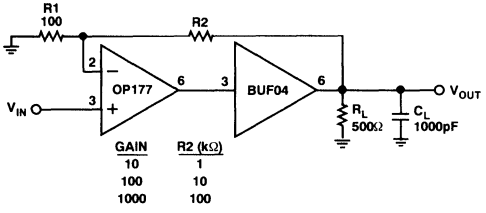

Figure 38. BUF04 as Booster Stage for a Precision Op Amp

Paralleling BUF04s for Increased Load Drive Capability

In applications where continuous output currents greater than 50 mA are required or where heat management is an issue, a number of BUF04s can be connected in parallel to reduce the drive requirement of any one buffer. An example of one such application is illustrated in Figure 39. In this circuit, the BUF04s are required to drive a doubly terminated 50 Ω line to ±5 V. This type of a load for a single BUF04 would certainly cause a power dissipation problem. Parallel operation results in lower input and output impedances and increased bias currents; on the other hand, input equivalent noise voltage is reduced and input offset voltage remains unchanged.

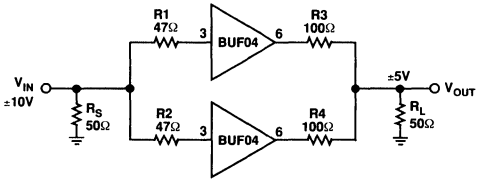

Figure 39. Paralleling BUF04s for High Output Currents

Overdrive Recovery and Phase Reversal

In applications where the inputs could be driven to the supply rails, the BUF04 recovers in 10 ns from positive or negative overdrive. The BUF04 does not exhibit any output voltage phase reversal when the input signal exceeds its input voltage range.

ANALOG DEVICES

Ultralow Offset Voltage Operational Amplifier

OP07

FEATURES

- Low V_{OS} ..... 25μV Max
- Low V_{OS} Drift ..... 0.6μV/°C Max
- Ultra-Stable vs Time ..... 1.0μV/Month Max
- Low Noise ..... 0.6μV_{p-p} Max
- Wide Input Voltage Range ..... ±14V
- Wide Supply Voltage Range ..... ±3V to ±18V
- Fits 725, 108A/308A, 741, AD510 Sockets
- 125° C Temperature-Tested Dice

ORDERING INFORMATION †

GENERAL DESCRIPTION

The OP-07 has very low input offset voltage (25μV max for OP-07A) which is obtained by trimming at the wafer stage. These low offset voltages generally eliminate any need for external nulling. The OP-07 also features low input bias current (±2nA for OP-07A) and high open-loop gain (300V/mV for OP-07A). The low offsets and high open-loop gain make the OP-07 particularly useful for high-gain instrumentation applications.

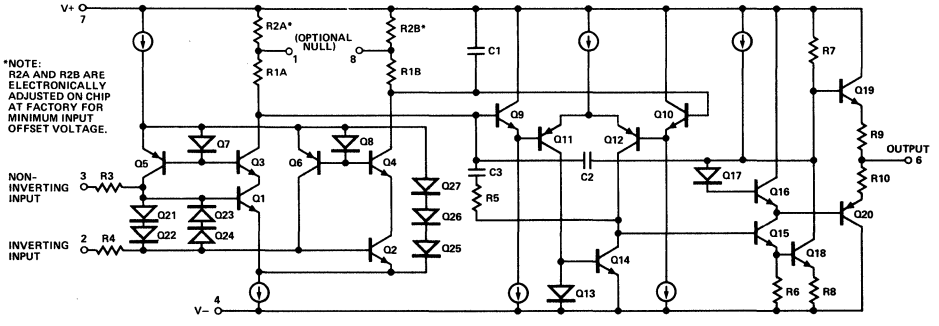
The wide input voltage range of ±13V minimum combined with high CMRR of 110dB (OP-07A) and high input impedace provides high accuracy in the noninverting circuit configuration. Excellent linearity and gain accuracy can be maintained even at high closed-loop gains.

Stability of offsets and gain with time or variations in temperture is excellent. The accuracy and stability of the OP-07, even at high gain, combined with the freedom from external nulling have made the OP-07 a new industry standard for instrumentation and military applications.

The OP-07 is available in five standard performance grades. The OP-07A and the OP-07 are specified for operation over the full military range of –55°C to +125°C; the OP-07E is specified for operation over the 0°C to +70°C range, and OP-07C and D over the –40°C to +85°C temperature range.

The OP-07 is available in hermetically-sealed TO-99 metal can or ceramic 8-pin Mini-DIP, and in epoxy 8-pin Mini-DIP. It is a direct replacement for 725, 108A, and OP-05 amplifiers; 741-types may be directly replaced by removing the 741's nulling potentiometer. The OP-207, a dual OP-07, is available for applications requiring close matching of two OP-07 amplifiers. For improved specifications, see the OP-77/OP-177.

SIMPLIFIED SCHEMATIC



This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

ABSOLUTE MAXIMUM RATINGS (Note 1)

Supply Voltage ..... ±22V
Differential Input Voltage ..... ±30V
Input Voltage (Note 2) ..... ±22V
Output Short-Circuit Duration ..... Indefinite
Storage Temperature Range
  J, RC and Z Packages ..... –65°C to +150°C
  P Package ..... –65°C to +125°C
Operating Temperature Range
  OP-07A, OP-07, OP-07RC ..... –55°C to +125°C
  OP-07E ..... 0°C to +70°C
  OP-07C, OP-07D ..... –40°C to +85°C
Lead Temperature (Soldering, 60 sec) ..... +300°C
Junction Temperature (T_j) ..... +150°C

PACKAGE TYPE	Θ_{JA} (Note 3)	Θ_{JC}	UNITS
TO-99 (J)	150	18	°C/W
8-Pin Hermetic DIP (Z)	148	16	°C/W
8-Pin Plastic DIP (P)	103	43	°C/W
20-Contact LCC	98	38	°C/W
8-Pin SO (S)	158	43	°C/W

NOTES:
1. Absolute maximum ratings apply to both DICE and packaged parts, unless otherwise noted.
2. For supply voltages less than ±22V, the absolute maximum input voltage is equal to the supply voltage.
3. Θ_{JA} is specified for worst case mounting conditions, i.e., Θ_{JA} is specified for device in socket for TO, CerDIP, P-DIP, and LCC packages; Θ_{JA} is specified for device soldered to printed circuit board for SO package.

ELECTRICAL CHARACTERISTICS at $V_S = \pm 15V$, $T_A = 25°C$, unless otherwise noted.

NOTES:
1. OP-07A grade V_{OS} is measured approximately one minute after application of power. For all other grades V_{OS} is measured approximately 0.5 seconds after application of power.
2. Long-Term Input Offset Voltage Stability refers to the averaged trend line of V_{OS} vs. Time over extended periods after the first 30 days of operation. Excluding the initial hour of operation, changes in V_{OS} during the first 30 operating days are typically 2.5µV — refer to typical performance curves. Parameter is sample tested.
3. Sample tested.
4. Guaranteed by design.

ELECTRICAL CHARACTERISTICS at $V_S = \pm 15V$, $-55°C \le T_A \le +125°C$, unless otherwise noted.

ANALOG DEVICES

Low Noise, Precision Operational Amplifier

OP27

FEATURES

- **Low Noise** ..... **80nV$_{p-p}$ (0.1Hz to 10Hz)**
  ..... **3nV/$\sqrt{Hz}$**
- **Low Drift** ..... **0.2μV/°C**
- **High Speed** ..... **2.8V/μs Slew Rate**
  ..... **8MHz Gain Bandwidth**
- **Low V_{OS}** **10μV**
- **Excellent CMRR** ..... **126dB at V_{CM} of ±11V**
- **High Open-Loop Gain** ..... **1.8 Million**
- **Fits 725, OP-07, OP-05, AD510, AD517, 5534A sockets**
- **Available in Die Form**

GENERAL DESCRIPTION

The OP-27 precision operational amplifier combines the low offset and drift of the OP-07 with both high speed and low noise. Offsets down to 25μV and drift of 0.6μV/°C maximum make the OP-27 ideal for precision instrumentation applications. Exceptionally low noise, $e_n = 3.5nV/\sqrt{Hz}$, at 10Hz, a low 1/f noise corner frequency of 2.7Hz, and high gain (1.8 million), allow accurate high-gain amplification of low-level signals. A gain-bandwidth product of 8MHz and a 2.8V/μsec slew rate provides excellent dynamic accuracy in high-speed data-acquisition systems.

A low input bias current of ±10nA is achieved by use of a bias-current-cancellation circuit. Over the military temperature range, this circuit typically holds I_B and I_{OS} to ±20nA and 15nA respectively.

The output stage has good load driving capability. A guaranteed swing of ±10V into 600Ω and low output distortion make the OP-27 an excellent choice for professional audio applications.

PSRR and CMRR exceed 120dB. These characteristics, coupled with long-term drift of 0.2μV/month, allow the circuit designer to achieve performance levels previously attained only by discrete designs.

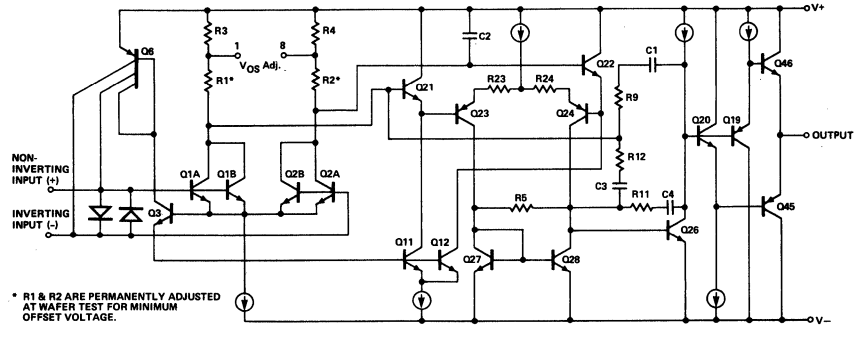
SIMPLIFIED SCHEMATIC



This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

Low cost, high-volume production of OP-27 is achieved by using an on-chip zener-zap trimming network. This reliable and stable offset trimming scheme has proved its effectiveness over many years of production history.

The OP-27 provides excellent performance in low-noise high-accuracy amplification of low-level signals. Applications include stable integrators, precision summing amplifiers, precision voltage-threshold detectors, comparators, and professional audio circuits such as tape-head and microphone preamplifiers.

The OP-27 is a direct replacement for 725, OP-06, OP-07 and OP-05 amplifiers; 741 types may be directly replaced by removing the 741's nulling potentiometer.

ABSOLUTE MAXIMUM RATINGS (Note 4)

PACKAGE TYPE	Θ_{JA} (Note 3)	Θ_{JC}	UNITS
TO-99 (J)	150	18	°C/W
8-Pin Hermetic DIP (Z)	148	16	°C/W
8-Pin Plastic DIP (P)	103	43	°C/W
20-Contact LCC (RC)	98	38	°C/W
8-Pin SO (S)	158	43	°C/W

NOTES:
1. For supply voltages less than ±22V, the absolute maximum input voltage is equal to the supply voltage.
2. The OP-27's inputs are protected by back-to-back diodes. Current limiting resistors are not used in order to achieve low noise. If differential input voltage exceeds ±0.7V, the input current should be limited to 25mA.
3. Θ_{JA} is specified for worst case mounting conditions, i.e., Θ_{JA} is specified for device in socket for TO, CerDIP, P-DIP, and LCC packages; Θ_{JA} is specified for device soldered to printed circuit board for SO package.
4. Absolute maximum ratings apply to both DICE and packaged parts, unless otherwise noted.

ELECTRICAL CHARACTERISTICS at $V_S = \pm 15V$, $T_A = 25°C$, unless otherwise noted.

PACKAGE TYPE	θ_{JA} (NOTE 3)	θ_{JC}	UNITS
TO-99 (J)	150	18	°C/W
8-Pin Hermetic DIP (Z)	148	16	°C/W
8-Pin Plastic DIP (P)	103	43	°C/W
20-Contact LCC (RC, TC)	98	38	°C/W
8-Pin SO (S)	158	43	°C/W

NOTES:
1. For supply voltages less than ±22V, the absolute maximum input voltage is equal to the supply voltage.
2. The OP-37's inputs are protected by back-to-back diodes. Current limiting resistors are not used in order to achieve low noise. If differential input voltage exceeds ±0.7V, the input current should be limited to 25mA.
3. θ_{JA} is specified for worst case mounting conditions, i.e., θ_{JA} is specified for device in socket for TO, CerDIP, P-DIP, and LCC packages; θ_{JA} is specified for device soldered to printed circuit board for SO package.
4. Absolute maximum ratings apply to both DICE and packaged parts, unless otherwise noted.

ELECTRICAL CHARACTERISTICS at $V_S = \pm 15V$, $T_A = 25°C$, unless otherwise noted.

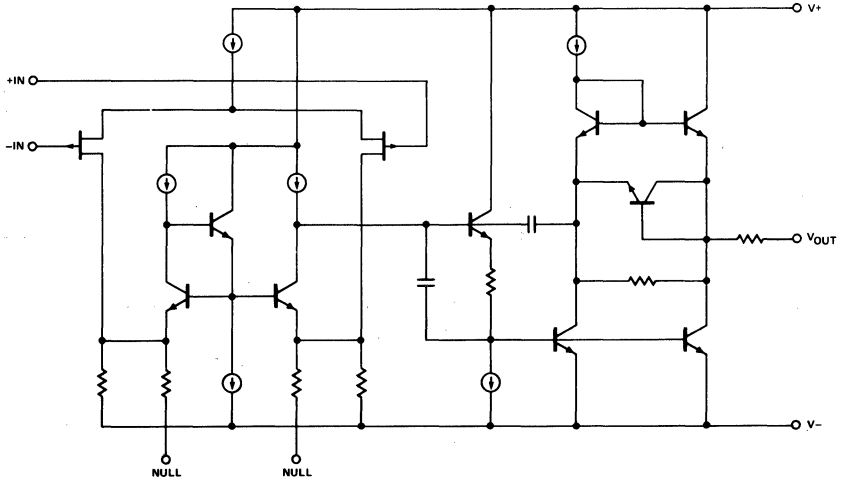
GENERAL DESCRIPTION

The OP-42 is a fast precision JFET-input operational amplifier. Similar in speed to the OP-17, the OP-42 offers a symmetric 58V/μs slew rate and is internally compensated for unity-gain operation. OP-42 speed is achieved with a supply current of less than 6mA. Unity-gain stability, a wide full-power bandwidth of 900kHz, and a fast settling-time of 800ns to 0.01% make the OP-42 an ideal output amplifier for fast digital-to-analog converters.

Equal attention was given to both speed and precision in the OP-42 design. Its tight 750μV maximum input offset voltage combined with well-controlled drift of less than 10μV/°C eliminates the need for external nulling in many circuits. The OP-42's

Continued

SIMPLIFIED SCHEMATIC



This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

GENERAL DESCRIPTION *Continued*

common-mode rejection of 88dB minimum over a ±11V input voltage range is exceptional for a high-speed amplifier. High CMR combined with a minimum 500V/mV gain into 10kΩ load ensure excellent linearity in both noninverting and inverting gain configurations. The low input bias and offset currents provided by the JFET input stage suit the OP-42 for use in high-speed sample and hold circuits, peak detectors, and log amplifiers. Excellent radiation hardness characteristics make the OP-42 ideal for military and aerospace applications.

The OP-42 conforms to the standard 741 pinout with nulling to V–. The OP-42 upgrades the performance of circuits using the AD544, AD611, AD711, and LF400 by direct replacement. In circuits without nulling, the OP-42 offers an upgrade for designs using the OP-16, OP-17, LT1022, LT1056, and HA2510.

Next Generation OP07, Ultralow Offset Voltage Operational Amplifier

OP77

FEATURES

- **Outstanding Gain Linearity**
- **Ultra High Gain ..... 5000V/mV Min**
- **Low V_{OS} Over Temperature ..... 60µV Max**
- **Excellent TCV_{OS} ..... 0.3µV/°C Max**
- **High PSRR ..... 3µV/V Max**
- **Low Power Consumption ..... 60mW Max**
- **Fits OP-07, 725, 108A/308A, 741 Sockets**
- **Available in Die Form**

* For devices processed in total compliance to MIL-SDT-883, add /883 after part number. Consult factory for 883 data sheet.

† Burn-in is available on commercial and industrial temperature range parts in CerDIP, plastic DIP, and TO-can packages.

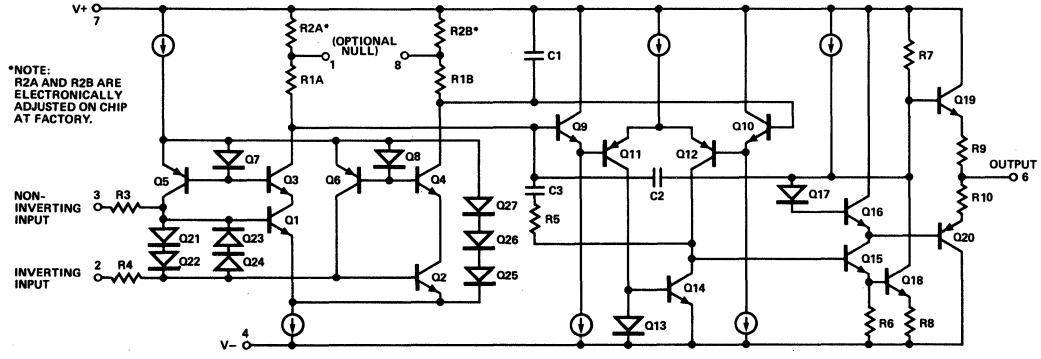
†† For availability and burn-in information on SO and PLCC packages, contact your local sales office.

GENERAL DESCRIPTION

The OP-77 significantly advances the state-of-the-art in precision op amps. The OP-77's outstanding gain of 10,000,000 or more is maintained over the full ±10V output range. This exceptional gain-linearity eliminates incorrectable system nonlinearities common in previous monolithic op amps, and provides superior performance in high closed-loop-gain applications. Low initial V_{OS} drift and rapid stabilization time, combined with only 50mW power consumption, are significant improvements over previous designs. These characteristics, plus the exceptional TCV_{OS} of 0.3µV/°C maximum and the low V_{OS} of 25µV maximum, eliminates the need for V_{OS} adjustment and increases system accuracy over temperature.

PSRR of 3µV/V (110dB) and CMRR of 1.0µV/V maximum virtually eliminiate errors caused by power supply drifts and common-mode signals. This combination of outstanding characteristics makes the OP-77 ideally suited for high-resolution instrumentation and other tight error budget systems. *Continued*

SIMPLIFIED SCHEMATIC



This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

This product is available in six standard grades and five standard packages: the TO-99 can, the 8-pin mini-DIP in ceramic, SO or epoxy, and the 20-contact LCC.

The OP-77 is a direct or upgrade replacement for the OP-07, 05, 725, or 108A op amps. 741-types can be replaced by eliminating the V_{OS} adjust pot. For higher precision performance refer to OP-177.

ABSOLUTE MAXIMUM RATINGS (Note 2)

Supply Voltage ..... ±22V
Differential Input Voltage ..... ±30V
Input Voltage (Note 1) ..... ±22V
Output Short-Circuit Duration ..... Indefinite
Storage Temperature Range
J, Z, and RC Packages ..... –65°C to +150°C
P Package ..... –65°C to +125°C
Operating Temperature Range
OP-77A, OP-77B (J, Z, RC) ..... –55°C to +125°C
OP-77E, OPP-77F (J, Z) ..... –25°C to +85°C
OP-77E, OP-77F, OP-77G (P, S) ..... 0°C to 70°
OP-77H (P, S) ..... –40°C to +85°C
Junction Temperature (T_j) ..... –65°C to +150C
Lead Temperature (Soldering, 60 sec.) ..... +300°C

PACKAGE TYPE	Θ_{jA} (Note 3)	Θ_{jC}	UNITS
TO-99 (J)	150	18	°C/W
8-Pin Hermetic DIP (Z)	148	16	°C/W
8-Pin Plastic DIP (P)	103	43	°C/W
20-Contact LCC (RC, TC)	98	38	°C/W
8-Pin SO (S)	158	43	°C/W

NOTES:
1. For supply voltages less than ±22V, the absolute maximum input voltage is equal to the supply voltage.
2. Absolute maximum ratings apply to both DICE and packaged parts, unless otherwise noted.
3. Θ_{jA} is specified for worst case mounting conditions, i.e., Θ_{jA} is specified for device in socket for TO, CerDIP, P-DIP, and LCC packages; Θ_{jA} is specified for device soldered to printed circuit board for SO package.

ELECTRICAL CHARACTERISTICS at V_S = ±15V, T_A = +25°C, unless otherwise noted.

NOTES:
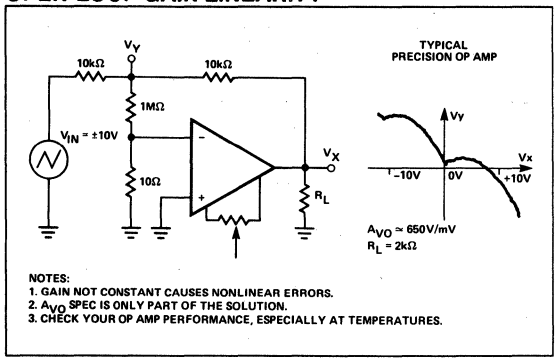
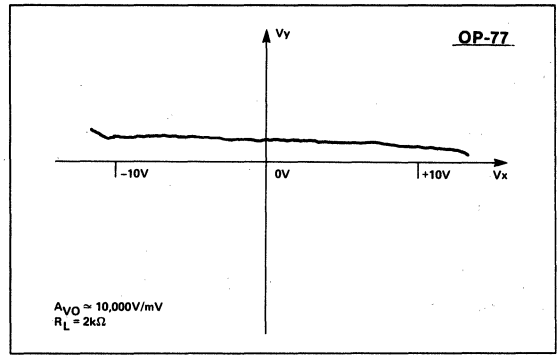
1. OP-77E: TCV_{OS} is 100% tested on J and Z packages.
2. Guaranteed by end-point limits.

OPEN-LOOP GAIN LINEARITY





Actual open-loop voltage gain can vary greatly at various output voltages. All automated testers use end-point testing and therefore only show the average gain. This causes errors in high closed-loop gain circuits. Since this is so difficult for manufacturers to test, you should make your own evaluation. This simple test circuit makes it easy. An ideal op amp would show a horizontal scope trace.

This is the output gain linearity trace for the new OP-77. The output trace is virtually horizontal at all points, assuring extremely high gain accuracy. The average open-loop gain is truly impressive – approximately 10,000,000.

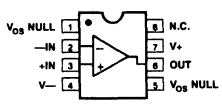
Precision, Low Voltage Micropower Operational Amplifier

OP90

FEATURES

- **Single/Dual Supply Operation ..... +1.6V to +36V**
  +0.8V to ±18V
- **True Single-Supply Operation; Input and Output Voltage Ranges Include Ground**
- **Low Supply Current ..... 20μA Max**
- **High Output Drive ..... 5mA Min**
- **Low Input Offset Voltage ..... 150μV Max**
- **High Open-Loop Gain ..... 700V/mV Min**
- **Outstanding PSRR ..... 5.6μV/V Max**
- **Standard 741 Pinout with Nulling to V–**
- **Available in Die Form**

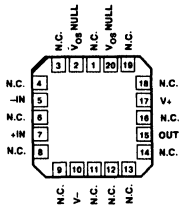
PIN CONNECTIONS



8-PIN HERMETIC DIP (Z-Suffix)

8-PIN EPOXY MINI-DIP (P-Suffix)

8-PIN SO (S-Suffix)



OP-90 ARC/883 LCC (RC-Suffix)

GENERAL DESCRIPTION

The OP-90 is a high performance micropower op amp that operates from a single supply of +1.6V to +36V or from dual supplies of ±0.8 to ±18V. Input voltage range includes the negative rail allowing the OP-90 to accommodate input signals down to ground in single supply operation. The OP-90's output swing also includes ground when operating from a single supply, enabling "zero-in, zero-out" operation.

The OP-90 draws less than 20μA of quiescent supply current, while able to deliver over 5mA of output current to a load. Input offset voltage is below 150μV eliminating the need for external nulling. Gain exceeds 700,000 and common-mode rejection is better than 100dB. The power supply-rejection ratio of under 5.6μV/V minimizes offset voltage changes experienced in battery powered systems.

The low offset voltage and high gain offered by the OP-90 bring precision performance to micropower applications. The minimal voltage and current requirements of the OP-90 suit it for battery and solar powered applications, such as portable instruments, remote sensors, and satellites.

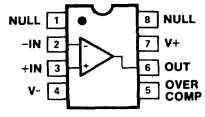
GENERAL DESCRIPTION

The OP-97 is a low-power alternative to the industry-standard OP-07 precision amplifier. The OP-97 maintains the standards of performance set by the OP-07 while utilizing only 600μA supply current, less than 1/6 that of an OP-07. Offset voltage is an ultra-low 25μV, and drift over temperature is below 0.6μV/°C. External offset trimming is not required in the majority of circuits.

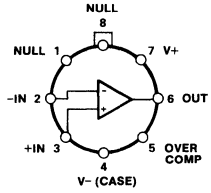
PIN CONNECTIONS



EPOXY MINI-DIP (P-Suffix)

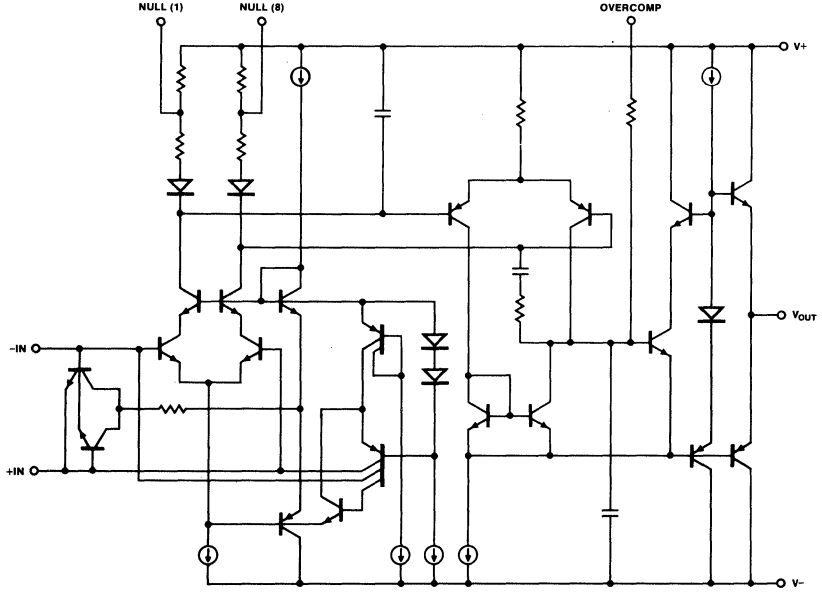
8-PIN CERDIP (Z-Suffix)

EPOXY SO†† (S-Suffix)



TO-99 (J-Suffix)

SIMPLIFIED SCHEMATIC



This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

Improvements have been made over OP-07 specifications in several areas. Notable is bias current, which remains below 250pA over the full military temperature range. The OP-97 is ideal for use in precision long-term integrators or sample-and-hold circuits that must operate at elevated temperatures.

Common-mode rejection and power-supply rejection are also improved with the OP-97, at 114dB minimum over wider ranges of common-mode or supply voltage. Outstanding PSR, a supply range specified from ±2.25V to ±20V and the OP-97's minimal power requirements combine to make the OP-97 a preferred device for portable and battery-powered instruments.

The OP-97 conforms to the OP-07 pinout, with the null potentiometer connected between pins 1 and 8 with the wiper to V+. The OP-97 will upgrade circuit designs using 725, OP05, OP07, OP12, and 1012 type amplifiers. It may replace 741-type amplifiers in circuits without nulling or where the nulling circuitry has been removed.

ABSOLUTE MAXIMUM RATINGS (Note 1)

Supply Voltage ..... ±20V
Input Voltage (Note 3) ..... ±20V

PACKAGE TYPE	Θ_{JA} (Note 2)	Θ_{JC}	UNITS
TO-99 (J)	150	18	°C/W
8-Pin Hermetic DIP (Z)	148	16	°C/W
8-Pin Plastic DIP (P)	103	43	°C/W
8-Pin SO (S)	158	43	°C/W

NOTES:
1. Absolute maximum ratings apply to both DICE and packaged parts, unless otherwise noted.
2. Θ_{JA} is specified for worst case mounting conditions, i.e., Θ_{JA} is specified for device in socket for TO, CerDIP, and P-DIP packages; Θ_{JA} is specified for device soldered to printed circuit board for SO package.
3. For supply voltages less than ±20V, the absolute maximum input voltage is equal to the supply voltage.
4. The OP-97's inputs are protected by back-to-back diodes. Current-limiting resistors are not used in order to achieve low noise. Differential input voltages greater than 1V will cause excessive current to flow through the input protection diodes unless limiting resistance is used.

ELECTRICAL CHARACTERISTICS at $V_S = \pm15V$, $V_{CM} = 0V$, $T_A = +25°C$, unless otherwise noted.

Low Noise, Low Drift Single-Supply Operational Amplifiers

OP-113/OP-213/OP-413*

FEATURES
Single- or Dual-Supply Operation
Low Noise: 4.7 nV/√Hz @ 1 kHz
Wide Bandwidth: 3.4 MHz
Low Offset Voltage: 100 μV
Very Low Drift: 0.2 μV/°C
Unity Gain Stable
No Phase Reversal

APPLICATIONS
Digital Scales
Multimedia
Strain Gages
Battery Powered Instrumentation
Temperature Transducer Amplifier

GENERAL DESCRIPTION

The OP-113 family dual operational amplifier features the lowest noise and drift of any single-supply amplifier. It has been designed for systems with internal calibration. Often these processor based systems are capable of calibrating corrections for offset and gain, but they cannot correct for temperature drifts and noise. Optimized for these parameters, the OP-113 family can be used to take advantage of superior analog performance combined with digital correction. Many systems using internal calibration operate from unipolar supplies, usually either +5 volts or +12 volts. The OP-113 family is designed to operate from single supplies from +4 volts to +36 volts, and to maintain its low noise and precision performance.

The OP-113 family is unity gain stable and has a typical gain bandwidth product of 3.4 MHz. Slew rate is in excess of 1 V/μs. Noise density is a very low 4.7 nV/√Hz, and noise in the 0.1 Hz to 10 Hz band is 120 nV p-p. Input offset voltage is guaranteed and offset drift is guaranteed to be less than 0.8 μV/°C. Input common-mode range includes the negative supply and to within 1 volt of the positive supply over the full supply range. Phase reversal protection is designed into the OP-113 family for cases where input voltage range is exceeded. Output voltage swings also include the negative supply and go to within 1 volt of the positive rail. The output is capable of sinking and sourcing current throughout its range and is specified with 600 Ω loads.

Digital scales and other strain gage applications benefit from the very low noise and low drift of the OP-113 family. Other applications include use as a buffer or amplifier for both A/D and D/A sigma-delta converters. Often these converters have high resolutions requiring the lowest noise amplifier to utilize their full potential. Many of these converters operate in either single-supply or low-supply voltage systems, and attaining the greater signal swing possible increases system performance. No other single supply amplifier provides better performance for these applications.

The OP-113 family is specified for single +5 volt and dual ±15 volt operation over the XIND—extended industrial (−40°C to +85°C) temperature range. They are available in plastic and ceramic 8-pin DIPs, plus SOIC-8 surface mount packages.

APPLICATIONS

The OP-113, OP-213 and OP-413 form a new family of high performance amplifiers that feature precision performance in standard dual supply configurations, and, more importantly, maintain precision performance when a single power supply is used. In addition to accurate dc specifications, it is the lowest noise single supply amplifier available with only 4.7 nV/$\sqrt{\text{Hz}}$ typical noise density.

Single supply applications have special requirements due to the generally reduced dynamic range of the output signal. Single supply applications are often operated at voltages of +5 volts or +12 volts, compared to dual supply applications with supplies of ±12 volts or ±15 volts. This results in reduced output swings. Where a dual supply application may often have 20 volts of signal output swing, single supply applications are limited to at most the supply range, and more commonly several volts below the supply. In order to attain the greatest swing the single supply output stage must swing closer to the supply rails than in dual supply applications.

The OP-113 family has a new patented output stage that allows the output to swing closer to ground, or the negative supply, than previous bipolar output stages. Previous op amps had outputs that could swing to within about ten millivolts of the negative supply in single supply applications. However the OP-113 family combines both a bipolar and a CMOS device in the output stage, enabling it to swing to within a few hundred microvolts of ground.

When operating with reduced supply voltages, the input range is also reduced. This reduction in signal range results in reduced signal-to-noise ratio, for any given amplifier. There are only two ways to improve this; increase the signal range or reduce the noise. The OP-113 family addresses both of these parameters. Input signal range is from the negative supply to within one volt of the positive supply over the full supply range. Competitive parts have input ranges that are a half a volt to five volts less than this. Noise has also been optimized in the OP-113 family. At 4.7 nV/$\sqrt{\text{Hz}}$, it is less than one fourth that of competitive devices.

Phase Reversal

The OP-113 family is protected against phase reversal as long as both of the inputs are within the supply ranges. However, if there is a possibility of either input going below the negative supply (or ground in the single supply case), then the inputs should be protected with a series resistor to limit input current to 2 mA.

OP-113 Offset Adjust

The OP-113 has the facility for external offset adjustment, using the industry standard arrangement. Pins 1 and 5 are used in conjunction with a potentiometer of 10 kΩ total resistance, connected with the wiper to V– (or ground in single supply applications). The total adjustment range is about ±2 mV using this configuration.

Adjusting the offset to zero has minimal effect on offset drift (assuming the potentiometer has a tempco of less than 1000 ppm/°C). Adjustment away from zero, however, (like all bipolar amplifiers) will result in a TCV_{OS} of approximately 3.3 μV/°C for every millivolt of induced offset.

It is, therefore, not generally recommended that this trim be used to compensate for system errors originating outside of the OP-113. The initial offset of the OP-113 is low enough that external trimming is almost never required, but if necessary, the 2 mV trim range may be somewhat excessive. Reducing the trimming potentiometer to a 2 kΩ value will give a more reasonable range of ±400 μV.

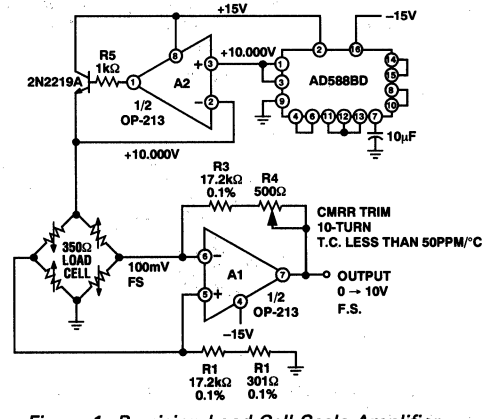

Figure 1. Precision Load Cell Scale Amplifier

APPLICATION CIRCUITS

A High Precision Industrial Load-Cell Scale Amplifier

The OP-113 family makes an excellent amplifier for conditioning a load-cell bridge. Its low noise greatly improves the signal resolution, allowing the load cell to operate with a smaller output range, thus reducing its nonlinearity. Figure 1 shows one half of the OP-113 family used to generate a very stable 10.000 V bridge excitation voltage while the second amplifier provides a differential gain. R4 should be trimmed for maximum common-mode rejection.

A Low Voltage Single Supply, Strain-Gage Amplifier

The true zero swing capability of the OP-113 family allows the amplifier in Figure 2 to amplify the strain-gage bridge accurately even with no signal input while being powered by a single +5 volt supply. A stable 4.000 V bridge voltage is made possible by the rail-to-rail OP-295 amplifier, whose output can swing to within a millivolt of either rail. This high voltage swing greatly increases the bridge output signal without a corresponding increase in bridge input.

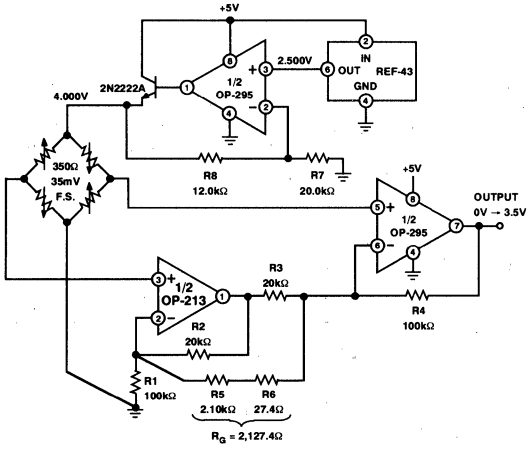

Figure 2. Single Supply Strain-Gage Amplifier

A High Accuracy Linearized RTD Thermometer Amplifier

Zero-suppressing the bridge facilitates simple linearization of the RTD by feeding back a small amount of the output signal to the RTD (Resistor Temperature Device). In Figure 3 the left leg of the bridge is servoed to a virtual ground voltage by amplifier A1, while the right leg of the bridge is also servoed to zero-volt by amplifier A2. This eliminates any error resulting from common-mode voltage change in the amplifier. A three-wire RTD is used to balance the wire resistance on both legs of the bridge, thereby reducing temperature mismatch errors. The 5.000 V bridge excitation is derived from the extremely stable AD588 reference device with 1.5 ppm/°C drift performance.

Linearization of the RTD is done by feeding a fraction of the output voltage back to the RTD in the form of a current. With just the right amount of positive feedback, the amplifier output will be linearly proportional to the temperature of the RTD.

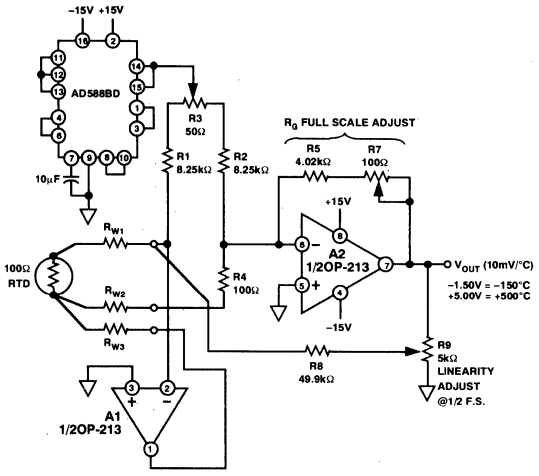

Figure 3. Ultraprecision RTD Amplifier

To calibrate the circuit, first immerse the RTD in a zero-degree ice bath or substitute an exact 100 Ω resistor in place of the RTD. Adjust the ZERO ADJUST potentiometer for a 0.000 V output, then set R9 LINEARITY ADJUST potentiometer to the middle of its adjustment range. Substitute a 280.9 Ω resistor (equivalent to 500°C) in place of the RTD, and adjust the FULL-SCALE ADJUST potentiometer for a full-scale voltage of 5.000 V.

To calibrate out the nonlinearity, substitute a 194.07 Ω resistor (equivalent to 250°C) in place of the RTD, then adjust the LINEARITY ADJUST potentiometer for a 2.500 V output. Check and readjust the full-scale and half-scale as needed.

Once calibrated, the amplifier outputs a 10 mV/°C temperature coefficient with an accuracy better than ±0.5°C over an RTD measurement range of −150°C to +500°C. Indeed the amplifier can be calibrated to a higher temperature range, up to 850°C.

A High Accuracy Thermocouple Amplifier

Figure 4 shows a popular K-type thermocouple amplifier with cold-junction compensation. Operating from a single +12 volt supply, the OP-113 family's low noise allows temperature measurement to better than 0.02°C resolution from 0°C to 1000°C range. The cold-junction error is corrected by using an inexpensive silicon diode as a temperature measuring device. It should be placed as close to the two terminating junctions as physically possible. An aluminum block might serve well as an isothermal system.

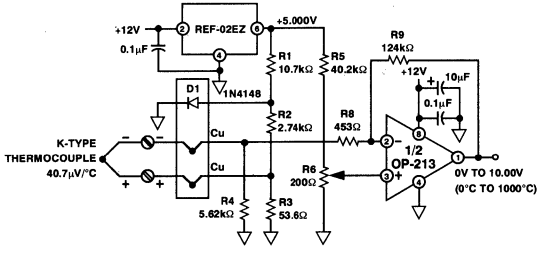

Figure 4. Accurate K-Type Thermocouple Amplifier

R6 should be adjusted for a zero-volt output with the thermocouple measuring tip immersed in a zero-degree ice bath. When calibrating, be sure to adjust R6 initially to cause the output to swing in the positive direction first. Then back off in the negative direction until the output just stops changing.

An Ultralow Noise, Single Supply Instrumentation Amplifier

Extremely low noise instrumentation amplifiers can be built using the OP-113 family. Such an amplifier that operates off a single supply is shown in Figure 5. Resistors R1–R5 should be of high precision and low drift type to maximize CMRR performance. Although the two inputs are capable of operating to zero volt, the gain of −100 configuration will limit the amplifier input common mode to not less than 0.33 V.

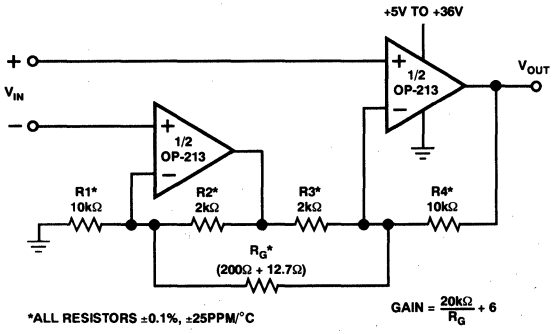

Figure 5. Ultralow Noise, Single Supply Instrumentation Amplifier

Supply Splitter Circuit

The OP-113 family has excellent frequency response characteristic that makes it an ideal pseudo-ground reference generator as shown in Figure 6. The OP-113 family serves as a voltage follower buffer. In addition, it drives a large capacitor that serves as a charge reservoir to minimize transient load changes, as well as a low impedance output device at high frequencies. The circuit easily supplies 25 mA load current with good settling characteristics.

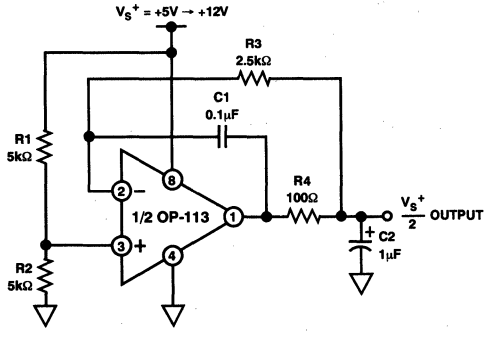

Figure 6. False Ground Generator

Low Noise Voltage Reference

Few reference devices combine low noise and high output drive capabilities. Figure 7 shows the OP-113 family used as a two-pole active filter that band limits the noise of the 2.500 V reference. Total noise measures 3 µV p-p.

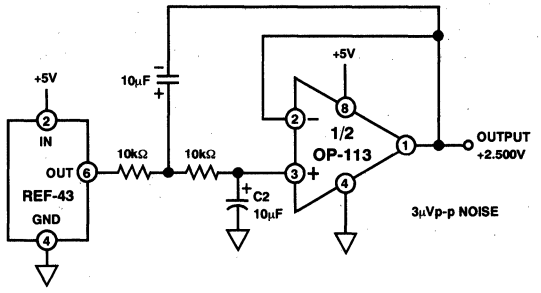

Figure 7. Low Noise Voltage Reference

+5 V Only Stereo DAC For Multimedia

The OP-113 family's low noise and single supply capability are ideally suited for stereo DAC audio reproduction or sound synthesis applications such as multimedia systems. Figure 8 shows an 18-bit stereo DAC output setup that is powered from a single +5 volt supply. The low noise preserves the 18-bit dynamic range of the AD1868. For DACs that operate on dual supplies, the OP-113 family can also be powered from the same supplies.

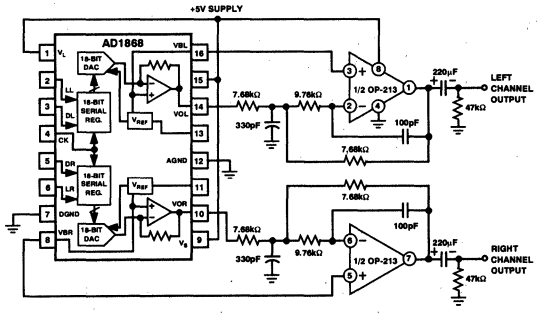

Figure 8. +5 V Only 18-Bit Stereo DAC

Low Voltage Headphone Amplifiers

Figure 9 shows a stereo headphone output amplifier for the AD1849 16-bit SoundPort® Stereo Codec device. The pseudo-reference voltage is derived from the common-mode voltage generated internally by the AD1849, thus providing a convenient bias for the headphone output amplifiers.

SoundPort is a registered trademark of Analog Devices, Inc.

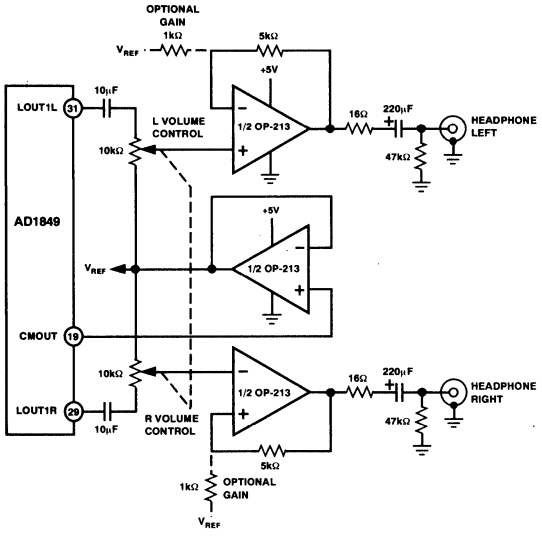

Figure 9. Headphone Output Amplifier for Multimedia Sound Codec

Low Noise Microphone Amplifier for Multimedia

The OP-113 family is ideally suited as a low noise microphone preamp for low voltage audio applications. Figure 10 shows a gain of 100 stereo preamp for the AD1849 16-bit SoundPort Stereo Codec chip. The common-mode output buffer serves as a "phantom power" driver for the microphones.

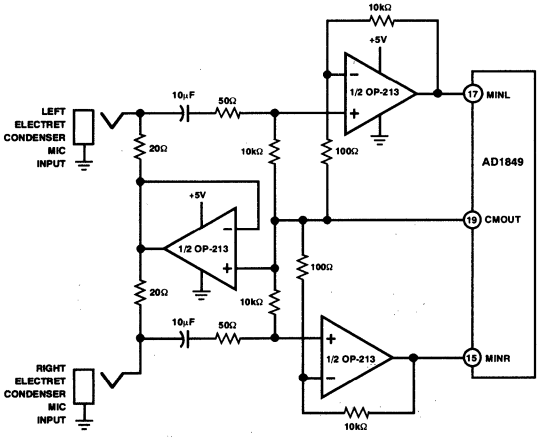

Figure 10. Low Noise Stereo Microphone Amplifier for Multimedia Sound Codec

Precision Voltage Comparator

With its PNP inputs and zero volt common-mode capability, the OP-113 family can make useful voltage comparators. There is only a slight penalty in speed in comparison to IC comparators. However, the significant advantage is its voltage accuracy. For example, V_{OS} can be a few hundred microvolts or less, combined with CMRR and PSRR exceeding 100 dB, while operating on 5 V supply. Standard comparators like the 111/311 family operate on 5 volts, but not with common-mode at ground, nor with offset below 3 mV. Indeed no commercially available single supply comparator has a V_{OS} less than 200 µV.

Figure 11 shows the OP-113 family response to a 10 mV overdrive signal when operating in open loop. The top trace shows the output rising edge has a 15 µs propagation delay, while the bottom trace shows a 7 µs delay on the output falling edge. This ac response is quite acceptable in many applications.

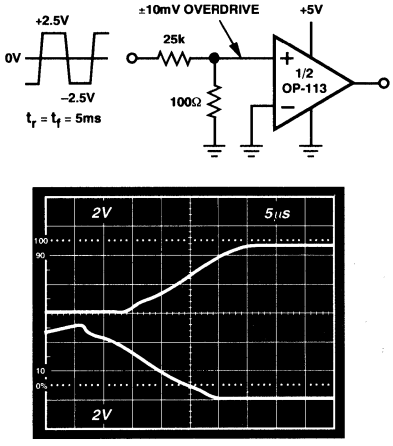

Figure 11. Precision Comparator

The low noise and 250 µV (maximum) offset voltage enhance the overall dc accuracy of this type of comparator. Note that zero crossing detectors and similar ground referred comparisons can be implemented even if the input swings to −0.3 volts below ground.

ANALOG DEVICES

Bipolar/JFET, Audio Operational Amplifier

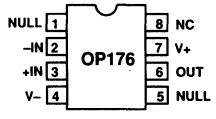
OP176*

FEATURES
Low Noise: 6 nV/√Hz
High Slew Rate: 25 V/μs
Wide Bandwidth: 10 MHz
Low Supply Current: 2.5 mA
Low Offset Voltage: 1 mV
Unity Gain Stable
SO-8 Package

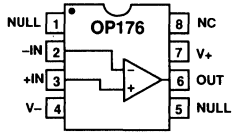
APPLICATIONS
Line Driver
Active Filters
Fast Amplifiers
Integrators

PIN CONNECTIONS

8-Lead Narrow-Body SO (S Suffix)



8-Lead Epoxy DIP (P Suffix)



GENERAL DESCRIPTION

The OP176 is a low noise, high output drive op amp that features the Butler Amplifier front-end. This new front-end design combines both bipolar and JFET transistors to attain amplifiers with the accuracy and low noise performance of bipolar transistors, and the speed and sound quality of JFETs. Total Harmonic Distortion plus Noise equals previous audio amplifiers, but at much lower supply currents.

Improved dc performance is also provided with bias and offset currents greatly reduced over purely bipolar designs. Input offset voltage is guaranteed at 1 mV and is typically less than 200 μV. This allows the OP176 to be used in many dc coupled or summing applications without the need for special selections or the added noise of additional offset adjustment circuitry.

The output is capable of driving 600 Ω loads to 10 V rms while maintaining low distortion. THD + Noise at 3 V rms is a low 0.0006%.

The OP176 is specified over the extended industrial (–40°C to +85°C) temperature range. OP176s are available in both plastic DIP and SO-8 packages. SO-8 packages are available in 2500 piece reels. Many audio amplifiers are not offered in SO-8 surface mount packages for a variety of reasons, however, the OP176 was designed so that it would offer full performance in surface mount packaging.

*Protected by U.S. Patent No. 5101126.

OP176GBC	+25°C	DICE	

*For outline information see Package Information section.

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the OP176 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

APPLICATIONS

Short Circuit Protection

The OP176 has been designed with output short circuit protection. The typical output drive current is ±50 mA. This high output current and wide output swing combine to yield an excellent audio amplifier, even when driving large signals, at low power and in a small package.

Total Harmonic Distortion

Total Harmonic Distortion + Noise (THD + N) of the OP176 is well below 0.001% with any load down to **600** Ω. However, this is dependent upon the peak output swing. In Figure 23 it is seen that the THD + Noise with 3 V rms output is below 0.001%. In the following Figure 24, THD + Noise is below 0.001% for the 10 kΩ and 2 kΩ loads but increases to above 0.01% for the 600 Ω load condition. This is a result of the output swing capability of the OP176. Notice the results in Figure 25, showing THD vs. V_{IN} (V rms).

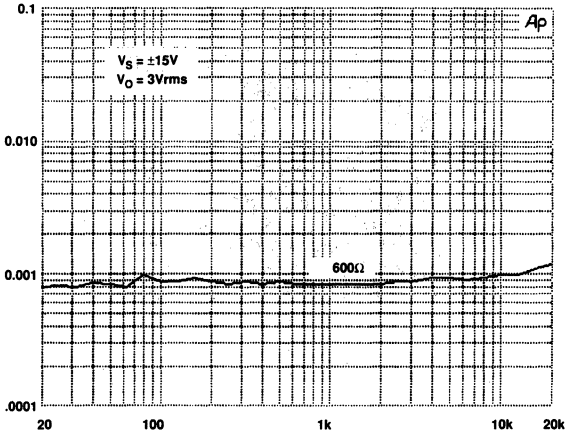

FIGURE 23. THD + Noise vs. Frequency

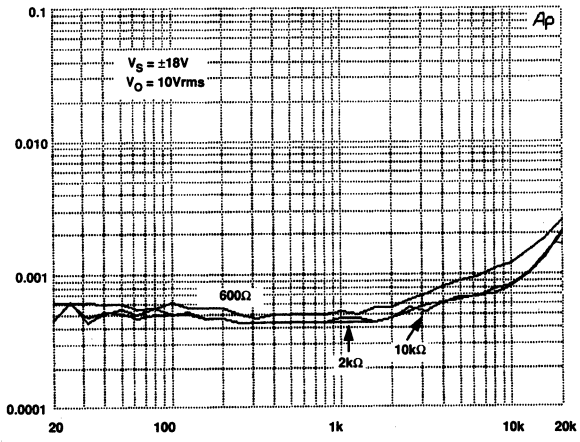

Figure 24. THD + Noise vs. R_{LOAD}

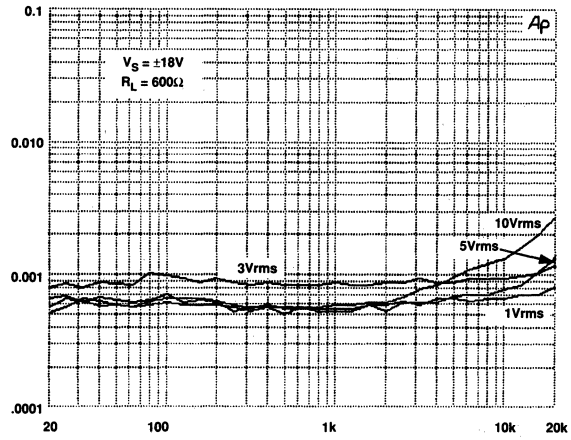

Figure 25. THD + Noise vs. Output Amplitude (V rms)

The output of the OP176 is designed to maintain low harmonic distortion while driving 600 Ω loads. However, driving 600 Ω loads with very high output swings results in higher distortion if clipping occurs.

To attain low harmonic distortion with large output swings, supply voltages may be increased. Figure 26 shows the performance of the OP176 driving 600 Ω loads with supply voltages varying from ±18 volts to ±20 volts. Notice that with ±18 volt supplies the distortion is fairly high, while with ±20 volt supplies it is a very low 0.0007%.

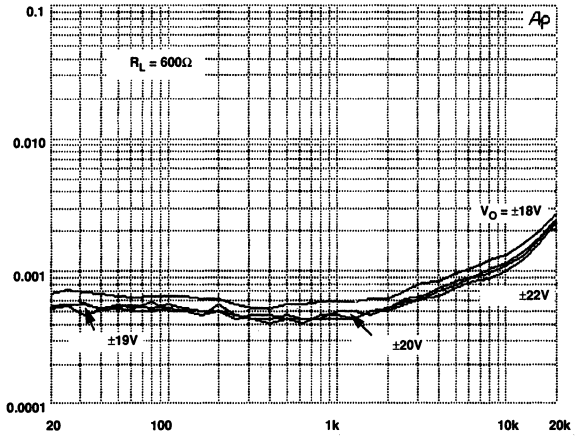

Figure 26. THD + Noise vs. Supply Voltage

Noise

The voltage noise density of the OP176 is below 6 nV/$\sqrt{\text{Hz}}$ from 30 Hz. This enables low noise designs to have good performance throughout the full audio range. Figure 27 shows a typical OP176 with a 1/f corner at 6 Hz.

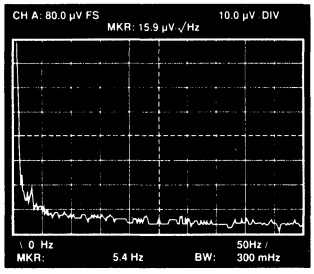

Figure 27. 1/f Noise Corner

Noise Testing

For audio applications the noise density is usually the most important noise parameter. For characterization the OP176 is tested using an Audio Precision, System One. The input signal to the Audio Precision must be amplified enough to measure accurately. For the OP176 the noise is gained by approximately 1020 using the circuit shown in Figure 28. Any readings on the Audio Precision must then be divided by the gain. In implementing this test fixture, good supply bypassing is essential.

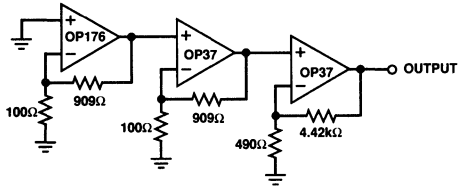

Figure 28. Noise Test

Upgrading "5534" Sockets

The OP176 is a superior amplifier for upgrading existing designs using the industry standard 5534. In most application circuits, the OP176 can directly replace the 5534 without any modifications to the surrounding circuitry. Like the 5534, the OP176 follows the industry standard, single op amp pinout. The difference between these two devices is the location of the null pins and the 5534's compensation capacitor.

The 5534 normally requires a 22 pF capacitor between Pins 5 and 8 for stable operation. Since the OP176 is internally compensated for unity gain operation, it does not require external compensation. Nevertheless, if the 5534 socket already includes a capacitor, the OP176 can be inserted without removing it. Since the OP176's Pin 8 is a "NO CONNECT" pin, there is no internal connection to that pin. Thus, the 22 pF capacitor would be electrically connected through Pin 5 to the internal nulling circuitry. With the other end left open, the capacitor should have no effect on the circuit. However, to avoid altogether any possibility for noise injection, it is recommended that the 22 pF capacitor be cut out of the circuit entirely.

If the original 5534 socket includes offset nulling circuitry, one would find a 10 kΩ to 100 kΩ potentiometer connected between Pins 1 and 8 with said potentiometer's wiper arm connected to V+. In order to upgrade the socket to the OP176, this circuit should be removed before inserting the OP176 for its offset nulling scheme uses Pins 1 and 5. Whereas the wiper arm of the 5534 trimming potentiometer is connected to the positive supply, the OP176's wiper arm is connected to the negative supply. Directly substituting the OP176 into the original socket would inject a large current imbalance into its input stage. In this case, the potentiometer should be removed altogether, or, if nulling is still required, the trimming potentiometer should be rewired to match the nulling circuit as illustrated in Figure 29.

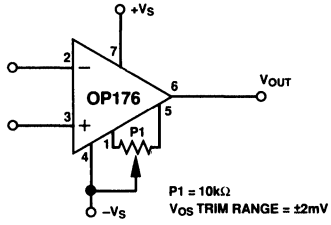

Figure 29. Offset Voltage Nulling Scheme

Input Overcurrent Protection

The maximum input differential voltage that can be applied to the OP176 is determined by a pair of internal Zener diodes connected across its inputs. They limit the maximum differential input voltage to ±7.5 V. This is to prevent emitter-base junction breakdown from occurring in the input stage of the OP176 when very large differential voltages are applied. However, in order to preserve the OP176's low input noise voltage, internal resistances in series with the inputs were not used to limit the current in the clamp diodes. In small signal applications, this is not an issue; however, in applications where large differential voltages can be inadvertently applied to the device, large transient currents can flow through these diodes. Although these diodes have been designed to carry a current of ±5 mA, external resistors as shown in Figure 30 should be used in the event that the OP176's differential voltage were to exceed ±7.5 V.

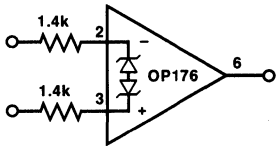

Figure 30. Input Overcurrent Protection

Output Voltage Phase Reversal

Since the OP176's input stage combines bipolar transistors for low noise and p-channel JFETs for high speed performance, the output voltage of the OP176 may exhibit phase reversal if either of its inputs exceeds the specified negative common-mode input voltage. This might occur in some applications where a transducer, or a system, fault might apply very large voltages upon the inputs of the OP176. Even though the input voltage range of the OP176 is ±10.5 V, an input voltage of approximately −13.5 V will cause output voltage phase reversal. In inverting amplifier configurations, the OP176's internal 7.5 V clamping diodes will prevent phase reversal; however, they will not prevent this effect from occurring in noninverting applications. For these applications, the fix is a 3.92 kΩ resistor in series with the noninverting input of the device and is illustrated in Figure 31.

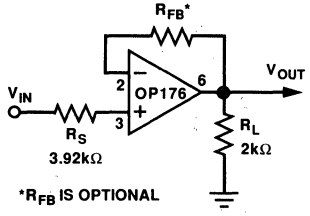

Figure 31. Output Voltage Phase Reversal Fix

Overdrive Recovery

The overdrive recovery time of an operational amplifier is the time required for the output voltage to recover to a rated output level from a saturated condition. This recovery time is important in applications where the amplifier must recover quickly after a large abnormal transient event. The circuit shown in Figure 32 was used to evaluate the OP176's overload recovery time. The OP176 takes approximately 1 µs to recover to V_{OUT} = +10 V and approximately 900 ns to recover to V_{OUT} = −10 V.

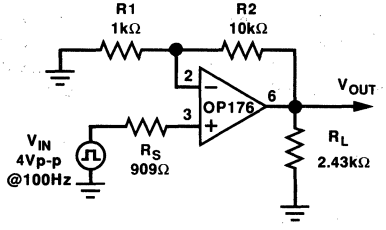

Figure 32. Overload Recovery Time Test Circuit

High Speed Operation

As with most high speed amplifiers, care should be taken with supply decoupling, lead dress, and component placement. Recommended circuit configurations for inverting and noninverting applications are shown in Figure 33 and Figure 34.

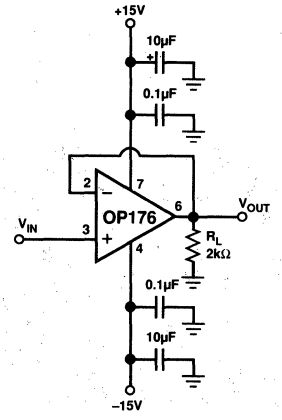

Figure 33. Unity Gain Follower

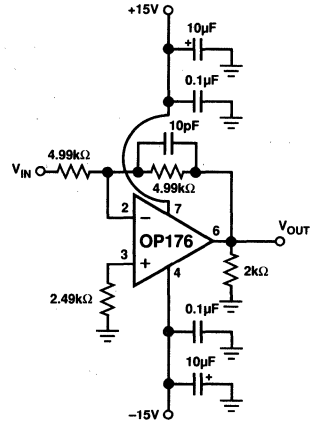

Figure 34. Unity Gain Inverter

In inverting and noninverting applications, the feedback resistance forms a pole with the source resistance and capacitance (R_S and C_S) and the OP176's input capacitance (C_{IN}), as shown in Figure 35. With R_S and R_F in the kΩ range, this pole can create excess phase shift and even oscillation. A small capacitor, C_{FB}, in parallel with R_{FB} eliminates this problem. By setting $R_S (C_S + C_{IN}) = R_{FB} C_{FB}$, the effect of the feedback pole is completely removed.

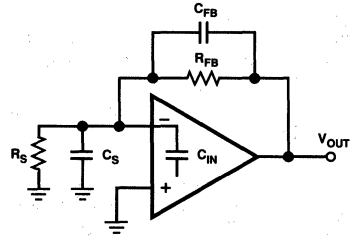

Figure 35. Compensating the Feedback Pole

Attention to Source Impedances Minimizes Distortion
Since the OP176 is a very low distortion amplifier, careful attention should be given to source impedances seen by both inputs. As with many FET-type amplifiers, the p-channel JFETs in the OP176's input stage exhibit a gate-to-source capacitance that varies with the applied input voltage. In an inverting configuration, the inverting input is held at a virtual ground and, as such, does not vary with input voltage. Thus, since the gate-to-source voltage is constant, there is no distortion due to input capacitance modulation. In noninverting applications, however, the gate-to-source voltage is not constant. The resulting capacitance modulation can cause distortion above 1 kHz if the input impedance is > 2 kΩ and unbalanced.

Figure 36 shows some guidelines for maximizing the distortion performance of the OP176 in noninverting applications. The best way to prevent unwanted distortion is to ensure that the parallel combination of the feedback and gain setting resistors (R_F and R_G) is less than 2 kΩ. Keeping the values of these resistors small has the added benefits of reducing the thermal noise of the circuit and dc offset errors. If the parallel combination of R_F and R_G is larger than 2 kΩ, then an additional resistor, R_S, should be used in series with the noninverting

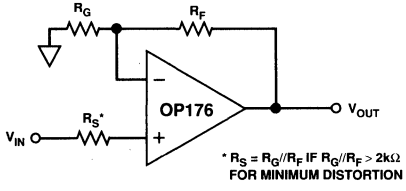

Figure 36. Balanced Input Impedance to Mininize Distortion in Noninverting Amplifier Circuits

input. The value of R_S is determined by the parallel combination of R_F and R_G to maintain the low distortion performance of the OP176. For a more generalized treatment on circuit impedances and their effects on circuit distortion, please review the section on Active Filters at the end of the Applications section.

Driving Capacitive Loads
As with any high speed amplifier, care must be taken when driving capacitive loads. The graph in Figure 14 shows the OP176's overshoot versus capacitive load. The test circuit is a standard noninverting voltage follower; it is this configuration that places the most demand on an amplifier's stability. For capacitive loads greater than 400 pF, overshoot exceeds 40% and is roughly equivalent to a 45° phase margin. If the application requires the OP176 to drive loads larger than 400 pF, then external compensation should be used.

Figure 37 shows a simple circuit which uses an in-the-loop compensation technique that allows the OP176 to drive any capacitive load. The equations in the figure allow optimization of the output resistor, R_X, and the feedback capacitor, C_F, for optimal circuit stability. One important note is that the circuit bandwidth is reduced by the feedback capacitor, C_F, and is given by:

$$BW = \frac{1}{2\pi R_F C_F}$$

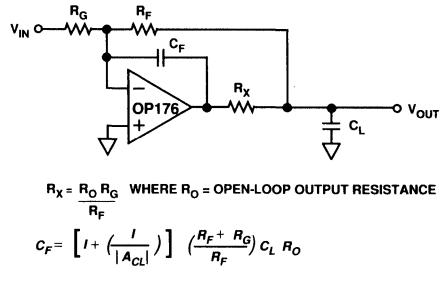

Figure 37. In-the-Loop Compensation Technique for Driving Capacitive Loads

APPLICATIONS USING THE OP176

A High Speed, Low Noise Differential Line Driver
The circuit of Figure 38 is a unique line driver widely used in many applications. With ±18 V supplies, this line driver can deliver a differential signal of 30 V p-p into a 2.5 kΩ load. The high slew rate and wide bandwidth of the OP176 combine to yield a full power bandwidth of 130 kHz while the low noise front end produces a referred-to-input noise voltage spectral density of 15 nV/√Hz. The circuit is capable of driving lower impedance loads as well. For example, with a reduced output level of 5 V rms (14 V p-p), the circuit exhibits a full-power bandwidth of 190 kHz while driving a differential load of 249 Ω! The design is a transformerless, balanced transmission system where output common-mode rejection of noise is of paramount importance. Like the transformer-based design, either output can be shorted to ground for unbalanced line driver applications without changing the circuit gain of 1. Other circuit gains can be set according to the equation in the diagram. This allows the design to be easily set for noninverting, inverting, or differential operation.

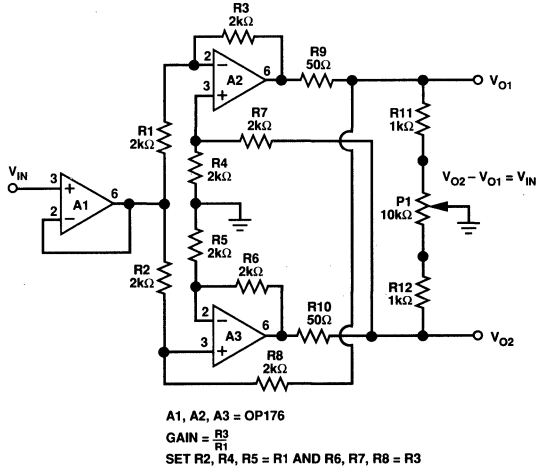

Figure 38. A High Speed, Low Noise Differential Line Driver

A Low Noise Microphone Preamplifier with a Phantom Power Option

Figure 39 is an example of a circuit that combines the strengths of the SSM2017 and the OP176 into a variable gain microphone preamplifier with an optional phantom power feature. The SSM2017's strengths lie in its low noise and distortion, and gain flexibility/simplicity. However, rated only for 2 kΩ or higher loads, this makes driving 600 Ω loads somewhat limited with the SSM2017 alone. A pair of OP176s are used in the circuit as a high current output buffer (U2) and a DC servo stage (U3). The OP176's high output current drive capability provides a high level drive into 600 Ω loads when operating from ±18 V supplies. For a complete treatment of the circuit design details, the interested reader should consult application note AN-242, available from Analog Devices.

This amplifier's performance is quite good over programmed gain ranges of 2 to 2000. For a typical audio load of 600 Ω, THD + N at various gains and an output level of 10 V rms is illustrated in Figure 40. For all but the very highest gain, the THD + N is consistent and well below 0.01%, while the gain of 2000 becomes more limited by noise. The noise performance of the circuit is exceptional with a referred-to-input noise voltage spectral density of 1 nV/√Hz at a circuit gain of 1000.

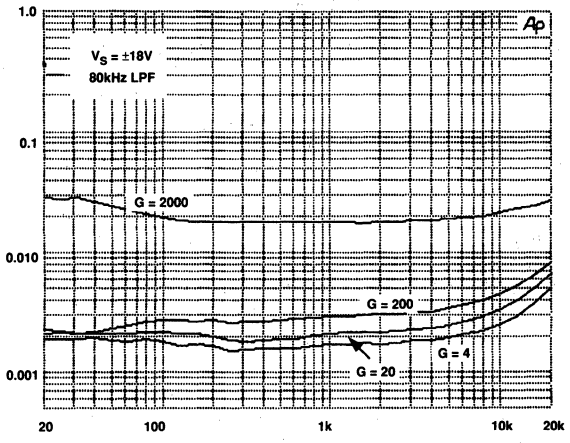

Figure 40. Low Noise Microphone Preamplifier THD + N Performance at Various Gains (V_{OUT} = 10 V rms and R_L = 600 Ω)

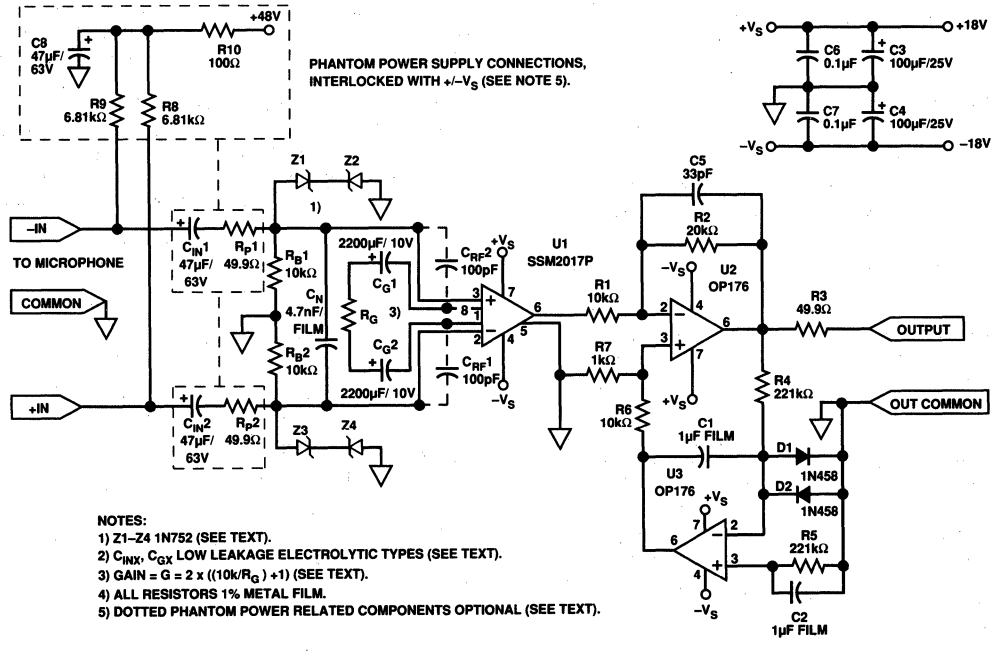

Figure 39. A Low Noise Microphone Preamplifier

A Low Noise, +5 V/+10 V Reference

In many high resolution applications, voltage reference noise can be a major contributor to overall system error. Monolithic voltage references often exhibit too much wide band noise to be used alone in these systems. Only through careful filtering and buffering of these monolithic references can one realize wide-band microvolt noise levels. The circuit illustrated in Figure 41 is an example of a low noise precision reference optimized for both ac and dc performance around the OP176. With a +10 V reference (the AD587), the circuit exhibits a 1 kHz spot output noise spectral density < 10 nV/$\sqrt{\text{Hz}}$. The reference output voltage is selectable between 5 V and 10 V, depending only on the selection of the monolithic reference. The output table illustrated in the figure provides a selection of monolithic references compatible with this circuit.

OUTPUT TABLE

V_{OUT}	U1	TOLERANCE (+/–mV)
10V	AD587	5 TO 10
10V	REF01	30 TO 100
10V	REF10	30 TO 50
10V	AD581	5 TO 30
5V	REF195	2 TO 10
5V	AD586	2.5 TO 20
5V	REF02	15 TO 50
5V	REF05	15 TO 25

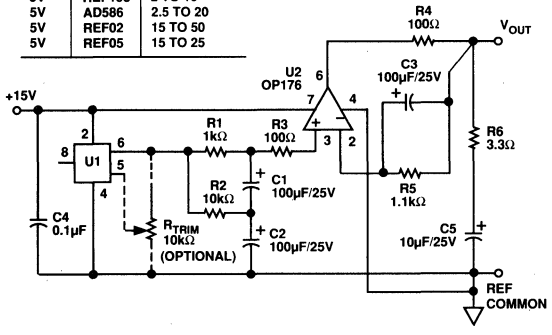

Figure 41. A Low Noise, +5 V/+10 V Reference

In operation, the basic reference voltage is set by U1, either a 5 V or 10 V 3-terminal reference chosen from the table. In this case, the reference used is a 10 V buried Zener reference, but all U1 IC types shown can plug into the pinout and can be optionally trimmed. The stable 10 V from the reference is then applied to the R1-C1-C2 noise filter, which uses electrolytic capacitors for a low corner frequency. When electrolytic capacitors are used for filtering, one must be cognizant of their dc leakage current errors. Here, however, a dc bootstrap of C1 is used, so this capacitor sees only the small R2 dc drop as bias, effectively lowering its leakage current to negligible levels. The resulting low noise, dc-accurate output of the filter is then buffered by a low noise, unity gain op amp using an OP176. With the OP176's low V_{OS} and control of the source resistances, the dc performance of this circuit is quite good and will not compromise voltage reference accuracy and/or drift. Also, the OP176 has a typical current limit of 50 mA, so it can provide higher output currents when compared to a typical IC reference alone.

A Differential ADC Driver

High performance audio sigma-delta ADCs, such as the stereo 16-bit AD1878 and the 18-bit AD1879, present challenging design problems with regards to input interfacing. Because of an internal switched capacitor input circuit, the ADC input structure presents a difficult dynamic load to the drive amplifier with fast transient input currents due to their 3 MHz ADC sampling rate. Also, these ADCs inputs are differential with a rated full-scale range of ±6.3 V, or about 4.4 V rms. Hence, the ADC interface circuit of Figure 42 is designed to accept a balanced input signal to drive the low dynamic impedances seen at the inputs of these ADCs. The circuit uses two OP176

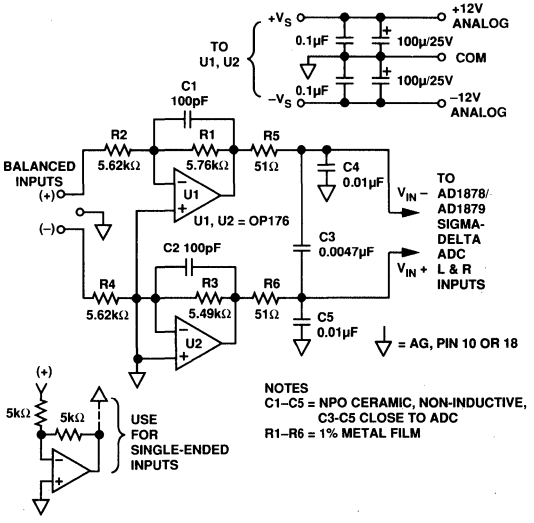

Figure 42. A Balanced Driver Circuit for Sigma-Delta ADCs

amplifiers as inverting low-pass filters for their speed and high output current drive. The outputs of the OP176s then drive the differential ADC inputs through an RC network. This RC network buffers the amplifiers against step changes at the ADC sampling inputs using one differential (C3) and two common-mode connected capacitors (C4 and C5). The 51 Ω series resistors isolate the OP176s from the heavily capacitive loads, while the capacitors absorb the transient currents. Operating on ±12 V supplies, this circuit exhibits a very low THD + N of 0.001% at 5 V rms outputs. For single-ended drive sources, a third op amp unity gain inverter can be added between R2's (+) input terminal and R4. For best results, short-lead, noninductive capacitors are suggested for C3, C4, and C5 (which are placed close to the ADC), and 1% metal-film types for R1 through R6. For surface mount PCBs, these components can be NPO ceramic chip capacitors and thin-film chip resistors.

An RIAA Phono Preamp

Figure 43 illustrates a simple phono preamplifier using RIAA equalization. The OP176 is used here to provide gain and is chosen for its low input voltage noise and high speed performance. The feedback equalization network (R1, R2, C1, and C2) forms a three time constant network, providing reasonably accurate equalization with standard component values. The input components terminate a moving magnet phono cartridge as recommended by the manufacturer, the element values shown being typical. When this ac coupled circuit is built with a low noise bipolar input device such as the OP176, amplifier bias current makes direct cartridge coupling difficult. This circuit uses input and output capacitor coupling to minimize biasing interactions.

Input ac coupling to the amplifier is provided via C5, and the low frequency termination resistance, R_T, is the parallel equivalent of R6 and R7. R3 of the feedback network is ac grounded via C4, a large value electrolytic. Additionally, this resistor is set to a low value to minimize circuit noise from nonamplifier sources. These design measures reduce the dc offset at the output of the OP176 to a few millivolts. The output coupling network of C3 and R4 is shown as suitable for wide band response, but it can be set to a 7950 µs time constant for use as a 20 Hz rumble filter.

The 1 kHz gain ("G") of this circuit, controlled by R3, is calculated as:

$$G\ (@\ 1\ kHz) = 0.101 \times \left(1 + \frac{R1}{R3}\right)$$

For an R3 of 200 Ω, the circuit gain is just under 50 × (≈ 34 dB), and higher gains are possible by decreasing R3. For any value of R3, the R5-C6 time constant should be equal to R3 and the series equivalent of C1 and C2.

Using readily available standard values for network elements (R1, R2, C1, and C2) makes the design easily reproducible and inexpensive. These components are ideally high quality precision types, for low equalization errors and minimum parasitics. One percent metal-film resistors and two percent film capacitors of polystyrene or polypropylene are recommended. Using the suggested values, the frequency response relative to the ideal RIAA characteristic is within ±0.2 dB over 20 Hz–20 kHz. Even tighter response can be achieved by using the alternate values, shown in brackets "[ ]," with the trade-off of a non off-the-shelf part.

As previously mentioned, the OP176 was chosen for three reasons: (1) For optimal circuit noise performance, the amplifier used should exhibit voltage and current noise densities of 5 nV/√Hz and 1 pA/√Hz, respectively. (2) For high gain accuracy, especially at high stage gains, the amplifier should exhibit a gain bandwidth product in excess of 5 MHz. (3) Equally important because of the 100% feedback through the network at high frequencies, the amplifier must be unity gain stable. With the OP176, the circuit exhibits low distortion over the entire range, generally well below 0.01% at outputs levels of 5 V rms using ±18 V supplies. To achieve maximum performance from this high gain, low level circuit, power supplies should be well regulated and noise free, and care should be taken with shielding and conductor layout.

Active Filter Circuits Using the OP176

A general active filter topology that lends itself to both high-pass (HP) and low-pass (LP) filters is the well known Sallen-Key (SK) VCVS (Voltage-Controlled, Voltage Source) architecture. This filter type uses the op amp as a fixed gain voltage follower at either unity or a higher gain. Discussed here are simplified 2-pole, unity gain forms of these filters, which are attractive for several reasons: One, at audio frequencies, using an amplifier with a 10 MHz bandwidth such as the OP176, these filters exhibit reasonably low sensitivities for unity gain and high damping (low Q). Second, as voltage followers, they are also inherently gain accurate within their pass band; hence, no gain resistor scaling errors are generated. Third, they can also be made "dc accurate," with output dc errors of only a few millivolts. The specific filter response in terms of HP, LP and damping is determined by the RC network around the op amp, as shown in Figure 44a.

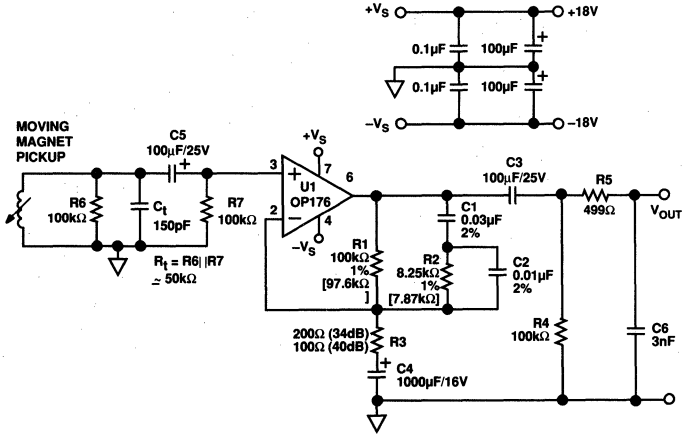

Figure 43. An RIAA Phono Preamplifier Circuit

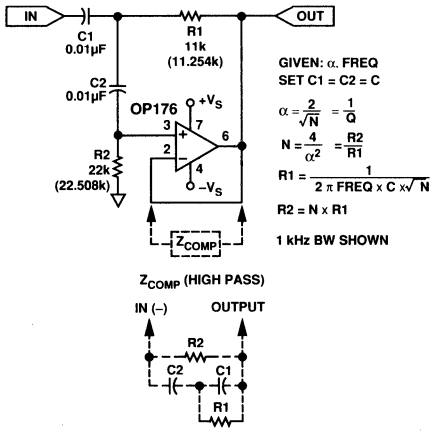
High Pass Sections

Figure 44a illustrates the high-pass form of a 2-pole SK filter using an OP176. For simplicity and practicality, capacitors C1 and C2 are set equal ("C"), and resistors R2 and R1 are adjusted to a ratio, N, which provides the filter damping coefficient, α, as per the design expressions. This high pass design is begun with selection of standard capacitor values for C1 and C2 and a calculation of N. The values for R1 and R2 are then determined from the following expressions:

$$R1 = \frac{1}{2\pi \times FREQ \times C \times \sqrt{N}}$$

and

$$R2 = N \times R1$$



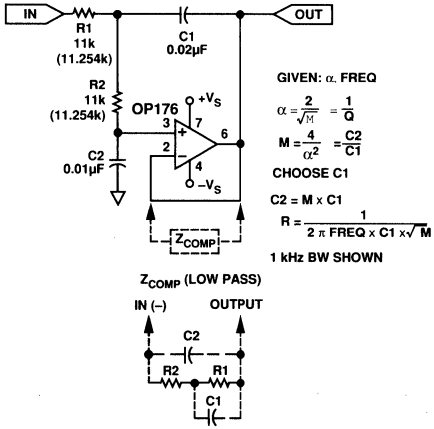
Figures 44a. Two-Pole Unity Gain HP/LP Active Filters

In this examples, circuit α (or 1/Q) is set equal to $\sqrt{2}$, providing a Butterworth (maximally flat) characteristic. The filter corner frequency is normalized to 1 kHz, with resistor values shown in both rounded and (exact) form. Various other 2-pole response shapes are possible with appropriate selection of α, and frequency can be easily scaled, using inversely proportional R or C values for a given α. The 22 V/µs slew rate of the OP176 will support 20 V p-p outputs above 100 kHz with low distortion. The frequency response resulting with this filter is shown as the dotted HP portion of Figure 45.

Low Pass Sections

In the LP SK arrangement of Figure 44b, the R and C elements are interchanged where the resistors are made equal. Here, the ratio of C2/C1 ("M") is used to set the filter α, as noted. Otherwise, this filter is similar to the HP section, and the resulting 1 kHz LP response is shown in Figure 45. The design begins with a choice of a standard capacitor value for C1 and a calculation of M. This then forces a value of "M × C1" for C2. Then, the value for R1 and R2 ("R") is calculated according to the following equation:

$$R = \frac{1}{2\pi \times FREQ \times C1 \times \sqrt{M}}$$



Figures 44b. Two-Pole Unity Gain HP/LP Active Filters

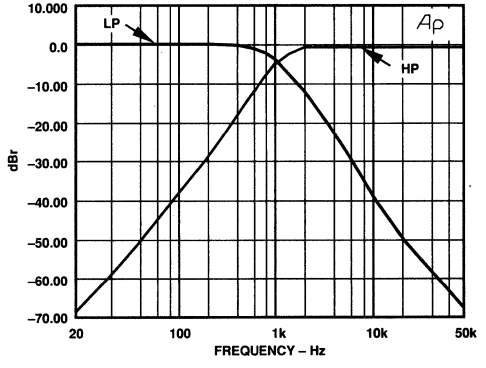


Figure 45. Relative Frequency Response of 2-Pole, 1 kHz Butterworth LP (Left) and HP (Right) Active Filters

Passive Component Selection for Active Filters

The passive components suitable for active filters deserve more than casual attention. Resistors should be 1%, low TC, metal-film types of the RN55 or RN60 style. Capacitors should be 1% or 2% film types preferably, such as polypropylene or polystyrene, or NPO (COG) ceramic for smaller values.

Active Filter Circuit Subtleties

In designing active filter circuits with the OP176, moderately low values (10 kΩ or less) for R1 and R2 can be used to minimize the effects of Johnson noise when critical. The practical tradeoff is, of course, capacitor size and expense. DC errors will result for larger values of resistance, unless compensation for amplifier input bias current is used. To add bias compensation in the HP filter section of Figure 42a, a feedback compensation resistor equal to R2 can be used. This will minimize bias current induced offset to the product of the OP176's I_{OS} and R2. For an R2 of 25 kΩ, this produces a typical compensated offset voltage of 50 µV. Similar compensation is applied to Figure 42b, using a resistance equal to R1+ R2. Using dc compensation, filter output dc errors using the OP176 will be dominated by its V_{OS}, which is typically 1 mV or less. A caveat here is that the additional resistors can increase noise substantially. For example, a 10 kΩ resistor generates ~ 12 nV/$\sqrt{Hz}$ of noise and is about twice that of the OP176. These resistors can be ac bypassed to eliminate their noise using a simple shunt capacitor chosen such that its reactance (X_C) is much less than R at the lowest frequency of interest.

A more subtle form of ac degradation is also possible in these filters, namely nonlinear input capacitance modulation. This issue was previously covered for general cases in the section on minimizing distortion. In active filter circuits, a fully compensating network (for both dc and ac performance) can be used to minimize this distortion. To be most effective, this network (Z_{COMP}) should include R1 through C2 as noted for either filter type, of the same style and value as their counterparts in the forward path. The effects of a Z_{COMP} network on the THD + N performance of two 1 kHz HP filters is illustrated in Figure 46. One filter (A) is the example shown in Figure 44a (Curves A1 and A2), while the second (B) uses RC values scaled 10 times upward in impedance (Curves B1 and B2). Both filters operate with a 2 V rms input, ±18 V supplies, 100 kΩ loading, and analyzer bandwidth of 80 kHz.

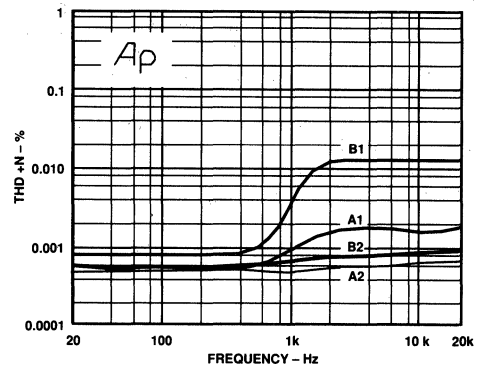

Figure 46. THD + N (%) vs. Frequency for Various 1 kHz HP Active Filters Illustrating the Effects of the Z_{COMP} Network

Curves A1 and B1 show performance with Z_{COMP} shorted, while curves A2 and B2 illustrate operation with Z_{COMP} active. For the "A" example values, distortion in the pass band of 1 kHz–20 kHz is below 0.001% compensated, and slightly higher uncompensated. With the higher impedance "B" network, there is a much greater difference between compensated and uncompensated responses, underscoring the sensitivity to higher impedances. Although the positive effect of Z_{COMP} is seen for both "A" and "B" cases, there is a buffering effect which takes place with lower impedances. As case "A" shows, when using larger capacitance values in the source, the amplifier's nonlinear C-V input characteristics have less effect on the signal.

Thus, to minimize the necessity for the complete Z_{COMP} compensation, effective filter designs should use the lowest capacitive impedances practical, with an 0.01 µF lower value limit as a goal for lowest distortion (while lower values can certainly be used, they may suffer higher distortion without the use of full compensation). Since most designs are likely to use low relative impedances for reasons of low noise and offset, the effects of CM distortion may or may not actually be apparent to a given application.

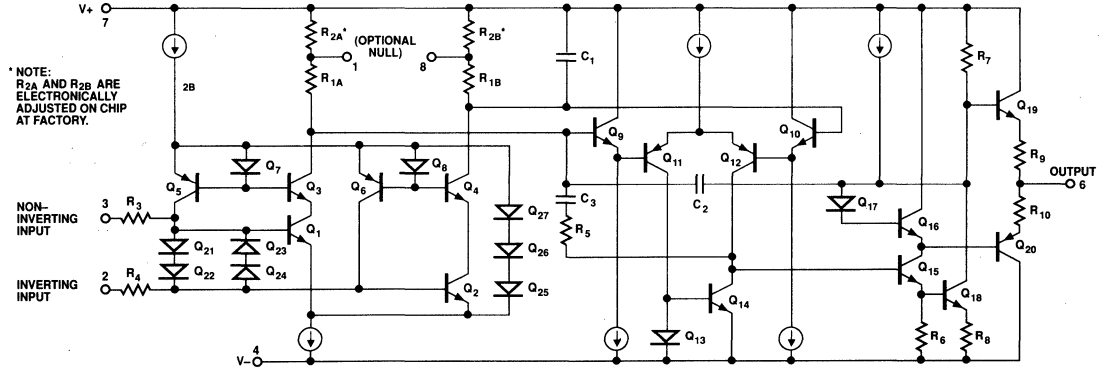
GENERAL DESCRIPTION

The OP-177 features the highest precision performance of any op amp currently available. Offset voltage of the OP-177 is only 10μV MAX at room temperature and 20μV MAX over the full military temperature range of −55°C to +125°C. The ultra-low V_{OS} of the OP-177, combines with its exceptional offset voltage drift (TCV_{OS}) of 0.1μV/°C MAX, to eliminate the need for external V_{OS} adjustment and increases system accuracy over temperature.

The OP-177's open-loop gain of 12V/μV is maintained over the full ±10V output range. CMRR of 130dB MIN, PSRR of 120dB MIN, and maximum supply current of 2mA are just a few examples of the excellent performance of this operational amplifier. The OP-177's combination of outstanding specifications insure accurate performance in high closed-loop gain applications.

This low noise bipolar input op amp is also a cost effective alternative to chopper-stabilized amplifiers. The OP-177 provides chopper-type performance without the usual problems of high noise, low frequency chopper spikes, large physical size, limited common-mode input voltage range, and bulky external storage capacitors.

Continued



GENERAL DESCRIPTION *Continued*

The OP-177 is offered in both the –55°C to +125°C military, and the –40°C to +85°C extended industrial temperature ranges. This product is available in 8-pin ceramic and epoxy DIPs, as well as the space saving 8-pin Small-Outline (SO) and the Leadless Chip Carrier (LCC) packages.

ABSOLUTE MAXIMUM RATINGS

Supply Voltage ..... ±22V
Differential Input Voltage ..... ±30V
Input Voltage (Note 1) ..... ±22V
Output Short-Circuit Duration ..... Indefinite
Storage Temperature Range
  Z and RC Packages ..... –65°C to +150°C
  P Package ..... –65°C to +125°C
Operating Temperature Range
  OP-177A, OP-177B ..... –55°C to +125°C
  OP-177E, OP-177F, OP-177G ..... –40°C to +85°C
Lead Temperature Range (Soldering, 60 sec) ..... 300°C
Junction Temperature (T_j) ..... –65°C to +150°C

PACKAGE TYPE	Θ_{JA} (NOTE 2)	Θ_{JC}	UNITS
8-Pin Hermetic DIP (Z)	148	16	°C/W
8-Pin Plastic DIP (P)	103	43	°C/W
20-Contact LCC (RC)	98	38	°C/W
8-Pin SO (S)	158	43	°C/W

NOTES:
1. For supply voltages less than ±22V, the absolute maximum input voltage is equal to the supply voltage.
2. Θ_{JA} is specified for worst case mounting conditions, i.e., Θ_{JA} is specified for device in socket for CerDIP, P-DIP, and LCC packages; Θ_{JA} is specified for device soldered to printed circuit board for SO package.

ELECTRICAL CHARACTERISTICS at V_S = ±15V, T_A = +25°C, unless otherwise noted.

5 MHz Single-Supply Operational Amplifiers

OP183/OP283

FEATURES
Single-Supply – +3 Volts to +36 Volts
Wide Bandwidth – 5 MHz
Low Offset Voltage – <1 mV
High Slew Rate – 10 V/μs
Low Noise – 10 nV/√Hz
Unity-Gain Stable
Input and Output Range Includes GND
No Phase Reversal

APPLICATIONS
Multimedia
Telecom
ADC Buffers
Wide Band Filters
Microphone Preamplifiers

GENERAL DESCRIPTION

The OP183 is a single-supply, 5 MHz bandwidth amplifier with slew rates of 10 V/μs. The OP283 is a dual version. Both can operate from voltages as low as 3 volts and up to 36 volts. This combination of slew rate and bandwidth yields excellent single-supply ac performance making them ideally suited for telecom and multimedia audio applications.

In addition to its ac characteristics, the OP183 family provides good dc performance with guaranteed 1 mV offset. Noise is a respectable 10 nV/√Hz. Supply current is only 1.2 mA per amplifier.

These amplifiers are well suited for single-supply applications that require moderate bandwidths even when used in high gain configurations. This makes them useful in filters and instrumentation. Their output drive capability and very wide full power bandwidth make them a good choice for multimedia headphone drivers or microphone input amplifiers.

The OP183 and OP283 are available in 8-pin plastic DIP and SO-8 surface mount packages. They are specified over the extended industrial (–40°C to +85°C) temperature range.

NOTE
Electrical tests and wafer probe to the limits shown. Due to variations in assembly methods and normal yield loss, yield after packaging is not guaranteed for standard product dice. Consult factory to negotiate specifications based on dice lot qualifications through sample lot assembly and testing.

ABSOLUTE MAXIMUM RATINGS[1]

Supply Voltage ..... ±18 V
Input Voltage ..... ±18 V
Differential Input Voltage[2] ..... ±7 V
Output Short-Circuit Duration to GND ..... Indefinite
Storage Temperature Range

APPLICATIONS

OP183 Offset Adjust

Figure 36 shows how the OP183's offset voltage can be adjusted by connecting a potentiometer between Pins 1 and 5, and connecting the wiper to V_{EE}. The recommended value for the potentiometer is 10 kΩ. This will give an adjustment range of approximately ±1 mV. If a larger adjustment span is desired, a 50 kΩ potentiometer will yield a range of ±2.5 mV.

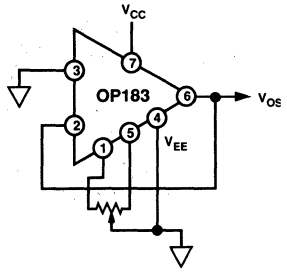

Figure 36. OP183 Offset Adjust

Phase Reversal

The OP183 family is protected against phase reversal as long as both of the inputs are within the range of the positive supply and the negative supply minus 0.6 volts. However if there is a possibility of either input going beyond these limits, then the inputs should be protected with a series resistor to limit input current to 2 mA.

Direct Access Arrangement

The OP183/OP283 can be used in a single supply Direct Access Arrangement (DAA) as is shown in Figure 37. This figure shows a portion of a typical DAA capable of operating from a single +5 volt supply and it should also work on +3 volt supplies with minor modifications. Amplifiers A2 and A3 are configured so that the transmit signal TXA is inverted by A2 and is not inverted by A3. This arrangement drives the transformer differentially so that the drive to the transformer is effectively doubled over a single amplifier arrangement. This application takes advantage of the OP183/283's ability to drive capacitive loads, and to save power in single supply applications.

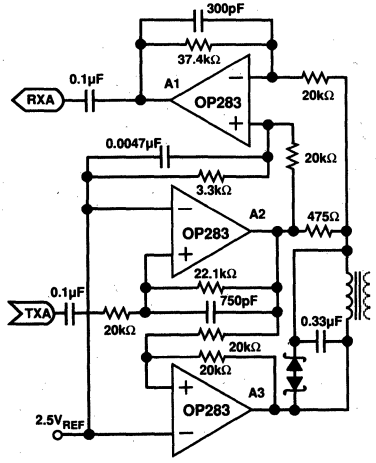

Figure 37. Direct Access Arrangement

+5 Volt Only Stereo DAC for Multimedia

The OP283's low noise and single supply capability are ideally suited for stereo DAC audio reproduction or sound synthesis applications such as multimedia systems. Figure 38 shows an 18-bit stereo DAC output setup that is powered from a single +5 volt supply. The low noise preserves the 18-bit dynamic range of the AD1868. For DACs that operate on dual supplies, the OP283 can also be powered from the same supplies.

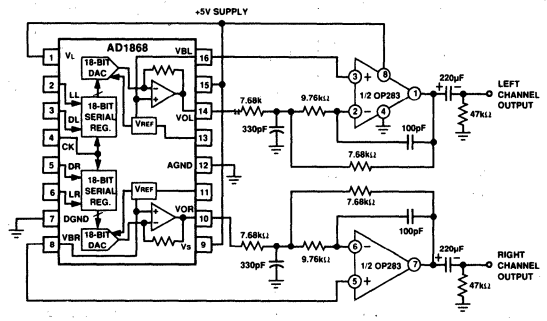

Figure 38. +5 Volt Only 18-Bit Stereo DAC

Low Voltage Headphone Amplifiers

Figure 39 shows a stereo headphone output amplifier for the AD1849 16-bit SoundPort® Stereo Codec device. The pseudo-reference voltage is derived from the common-mode voltage generated internally by the AD1849, thus providing a convenient bias for the headphone output amplifiers.

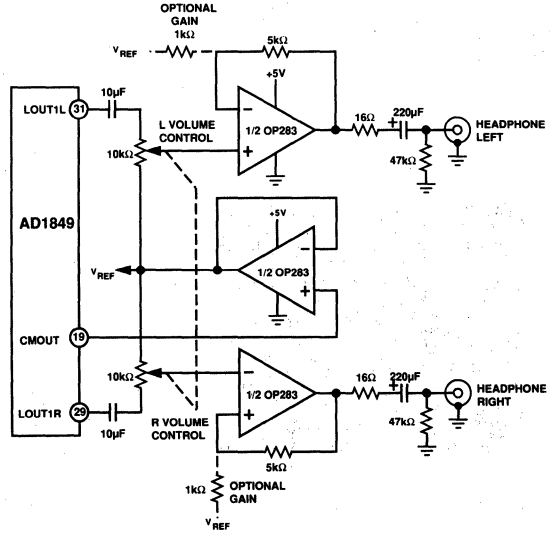

Figure 39. Headphone Output Amplifier for Multimedia Sound Codec

SoundPort is a registered trademark of Analog Devices Inc.

Low Noise Microphone Amplifier for Multimedia

The OP183 family is ideally suited as a low noise microphone preamp for low voltage audio applications. Figure 40 shows a gain of 100 stereo preamp for the AD1849 16-bit SoundPort Stereo Codec chip. The common-mode output buffer serves as a "phantom power" driver for the microphones.

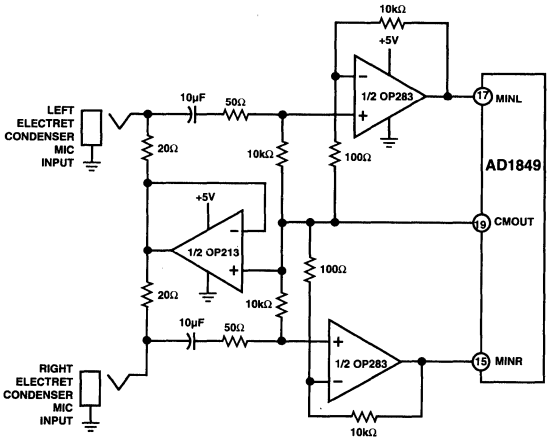

Figure 40. Low Noise Stereo Microphone Amplifier for Multimedia Sound CODEC

A +3 Volt 50 Hz/60 Hz Active Notch Filter with False Ground

To process ac signals, it may be easier to use a false-ground bias rather than the negative supply as a reference ground. This would reject the power-line frequency interference which oftentimes can obscure low frequency physiological signals, such as heart rates, blood pressures, EEGs, ECGs, et cetera.

Figure 41 shows a 50 Hz/60 Hz active notch filter for eliminating line noise in patient monitoring equipment. It has several kilohertz bandwidth and is not sensitive to false-ground perturbations. The simple false-ground circuit shown achieves good rejection of low frequency interference using standard off-the-shelf components.

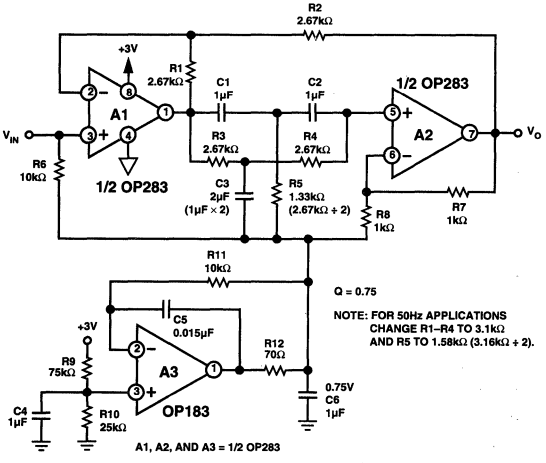

Figure 41. +3 Volt Supply 50 Hz/60 Hz Notch Filter with Pseudo Ground

A Low Voltage Frequency Synthesizer for Wireless Transceiver

The OP183's low noise and the low voltage operation capability serves well for the loop filter of a frequency synthesizer. Figure 42 shows a typical application in a radio transceiver. The phase noise performance of the synthesizer depends on low noise contribution from each component in the loop as the noise is amplified by the frequency division factor of the prescaler.

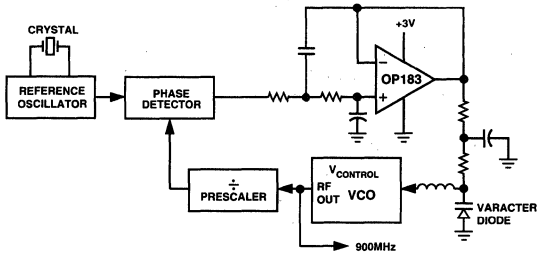

Figure 42. A Low Voltage Frequency Synthesizer for a Wireless Transceiver

The resistors used in the low-pass filter should be of low to moderate values to reduce noise contribution due to the input bias current as well as the resistors themselves. The filter cutoff frequency should be chosen to optimize the loop constant.

The filter section uses an OP283 dual op amp in a twin-T configuration whose frequency selectivity is very sensitive to the relative matching of the capacitors and resistors in the twin-T section. Mylar is the material of choice for the capacitors, and the relative matching of the capacitors and resistors determines the filter's pass band symmetry. Using 1% resistors and 5% capacitors produces satisfactory results.

Amplifier A3 biases A1 and A2 to the middle of their input common-mode range. When operating on a +3 V supply, the center of the OP283's common-mode range is 0.75 V. This notch filter effectively squelches 60 Hz pickup at a filter Q of 0.75. To reject 50 Hz interference, simply change the resistors in the twin-T section (R1 through R5) from 2.67 kΩ to 3.16 kΩ.

GENERAL DESCRIPTION

The OP-200 is the first monolithic dual operational amplifier to offer OP-77 type precision performance. Available in the industry standard 8-pin pinout, the OP-200 combines precision performance with the space and cost savings offered by a dual amplifier.

The OP-200 features an extremely low input offset voltage of less than 75μV with a drift below 0.5μV/°C, guaranteed over the

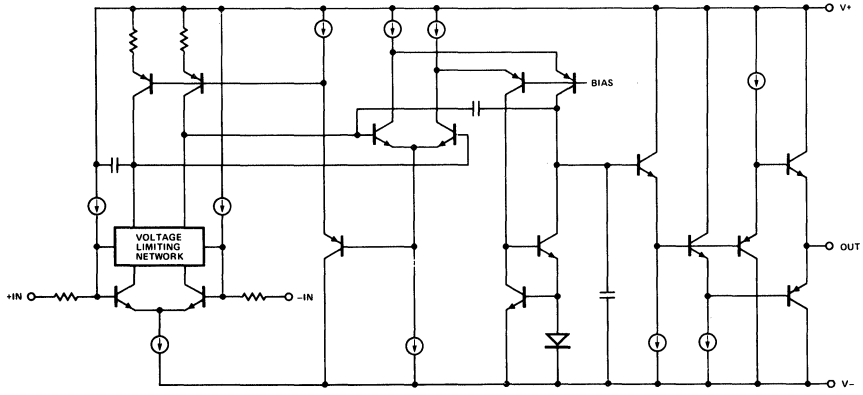
SIMPLIFIED SCHEMATIC (One of two amplifiers is shown.)



This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

full military temperature range. Open-loop gain of the OP-200 exceeds 5,000,000 into a 10kΩ load; input bias current is under 2nA; CMR is over 120dB and PSRR below 1.8μV/V. On-chip zener-zap trimming is used to achieve the extremely low input offset voltage of the OP-200 and eliminates the need for offset nulling.

Power consumption of the OP-200 is very low, with each amplifier drawing less than 725μA of supply current. The total current drawn by the dual OP-200 is less than one-half that of a single OP-07, yet the OP-200 offers significant improvements over this industry standard op amp. The voltage noise density of the OP-200, 11nV/$\sqrt{Hz}$ at 1kHz, is half that of most competitive devices.

The OP-200 is pin compatible with the OP-14, OP-221, LM158, MC1458/1558, and LT1013 and can be used to upgrade systems using these devices. The OP-200 is an ideal choice for applications requiring multiple precision op amps and where low power consumption is critical.

For a quad precision op amp, see the OP-400.

GENERAL DESCRIPTION

The OP-220 is a monolithic dual operational amplifier that can be used either in single or dual supply operation. The low offset voltage, and input offset voltage tracking as low as 1.0μV/°C, make this the first micropower precision dual operational amplifier.

The excellent specifications of the individual amplifiers combined with the tight matching and temperature tracking between channels provides high performance in instrumentation amplifier designs. The individual amplifiers feature extremely low input offset voltage, low offset voltage drift, low noise voltage, and low bias current. They are fully compensated and protected.

Matching between channels is provided on all critical parameters including input offset voltage, tracking of offset voltage vs. temperature, non-inverting bias currents, and common-mode rejection ratios.

GENERAL DESCRIPTION

The OP-221 is a monolithic dual operational amplifier that can be used either in single or dual supply operation. The wide supply voltage range, wide input voltage range, and low supply current drain of the OP-221 make it well-suited for operation from batteries or unregulated power supplies.

The excellent specifications of the individual amplifiers combined with the tight matching and temperature tracking between channels provide high performance in instrumentation amplifier designs. The individual amplifiers feature very low input offset voltage, low offset voltage drift, low noise voltage, and low bias current. They are fully compensated and protected.

Matching between channels is provided on all critical parameters including input offset voltage, tracking of offset voltage vs. temperature, non-inverting bias currents, and common-mode rejection.

NOTES:
1. $\Delta CMRR$ is $20 \log_{10} V_{CM}/\Delta CME$, where V_{CM} is the voltage applied to both noninverting inputs and ΔCME is the difference in common-mode input-referred error.
2. ΔPSRR is: $\frac{\text{Input-Referred Differential Error}}{\Delta V_S}$

Dual, Precision JFET High Speed Operational Amplifier

OP249

FEATURES

- Fast Slew Rate ..... 22V/μs Typ
- Settling Time (0.01%) ..... 1.2μs Max
- Offset Voltage ..... 300μV Max
- High Open-Loop Gain ..... 1000V/mV Min
- Low Total Harmonic Distortion ..... 0.002% Typ
- Improved Replacement for AD712, LT1057, OP-215, TL072, and MC34082
- Available in Die Form

APPLICATIONS

- Output Amplifier for Fast D/As
- Signal Processing
- Instrumentation Amplifiers
- Fast Sample/Holds
- Active Filters
- Low Distortion Audio Amplifiers
- Input Buffer for A/D Converters
- Servo Controllers

GENERAL DESCRIPTION

The OP-249 is a high-speed, precision dual JFET op amp, similar to the popular single op amp, the OP-42. The OP-249 outperforms available dual amplifiers by providing superior speed with excellent DC performance. Ultra-high open-loop gain (1kV/mV minimum), low offset voltage, and superb gain linearity, makes the OP-249 the industry's first true precision, dual high-speed amplifier.

With a slew rate of 22V/μs typical, and a fast settling time of less than 1.2μs maximum to 0.01%, the OP-249 is an ideal choice for high-speed bipolar D/A and A/D converter applications. The excellent DC performance of the OP-249 allows the full accuracy of high-resolution CMOS D/As to be realized.

Symmetrical slew rate, even when driving large loads, such as 600Ω, or 200pF of capacitance, and ultra-low distortion, make the OP-249 ideal for professional audio applications, active filters, high-speed integrators, servo systems, and buffer amplifiers.

The OP-249 provides significant performance upgrades to the TL072, AD712, OP-215, MC34082 and the LT1057.

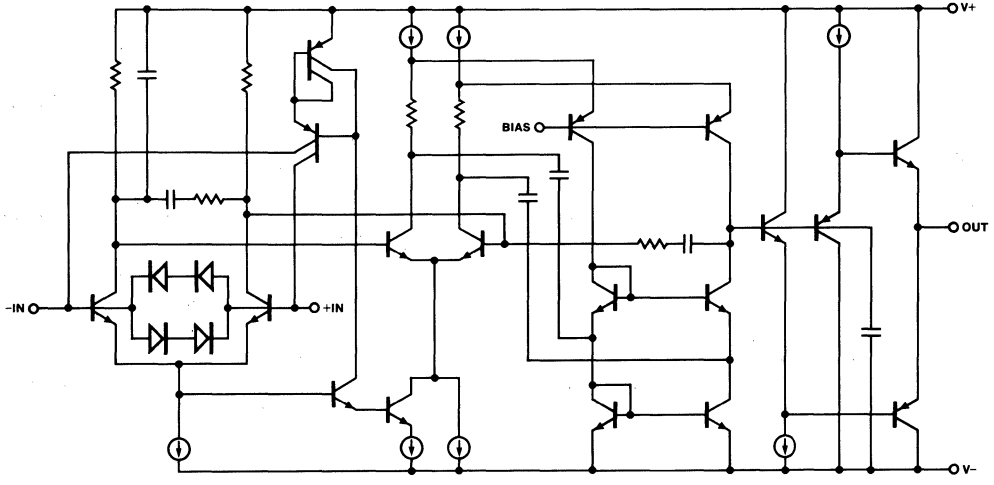
GENERAL DESCRIPTION

The OP-270 is a high-performance monolithic dual operational amplifier with exceptionally low voltage noise, 5nV/$\sqrt{Hz}$ at 1kHz Max, offering comparable performance to PMI's industry standard OP-27.

The OP-270 features an input offset voltage below 75μV and an offset drift under 1μV/°C, guaranteed over the full military temperature range. Open-loop gain of the OP-270 is over 1,500,000 into a 10kΩ load insuring excellent gain accuracy and linearity, even in high-gain applications. Input bias current is under 20nA which reduces errors due to signal source resistance. The OP-270's CMR of over 106dB and PSRR of less than 3.2μV/V significantly reduce errors due to

SIMPLIFIED SCHEMATIC (One of two amplifiers is shown.)



This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

ground noise and power supply fluctuations. Power consumption of the dual OP-270 is one-third less than two OP-27s, a significant advantage for power conscious applications. The OP-270 is unity-gain stable with a gain-bandwidth product of 5MHz and a slew rate of 2.4V/μs.

The OP-270 offers excellent amplifier matching which is important for applications such as multiple gain blocks, low-noise instrumentation amplifiers, dual buffers, and low-noise active filters.

The OP-270 conforms to the industry standard 8-pin DIP pinout. It is pin compatible with the MC1458/1558, SE5532/A, RM4558 and HA5102 dual op amps and can be used to upgrade systems using these devices.

For higher speed applications the OP-271, with a slew rate of 8V/μs, is recommended. For a quad op amp, see the OP-470.

GENERAL DESCRIPTION

The OP-271 is a unity-gain stable monolithic dual op amp featuring excellent speed, 8.5V/μs typical, and fast settling time, 2μs typical to 0.01%. The OP-271 has a gain-bandwidth of 5MHz with a high phase margin of 62°.

Input offset voltage of the OP-271 is under 200μV with input offset voltage drift below 2μV/°C, guaranteed over the full military temperature range. Open-loop gain exceeds 400,000 into a 10kΩ load ensuring outstanding gain accuracy and linearity. The input bias current is under 20nA limiting errors due to source resistance. The OP-271's outstanding CMR, over 106dB, and low PSRR, under 5.6μV/V, reduce errors caused by ground noise and power supply fluctuations. In addition, the OP-271 exhibits high CMR and PSRR over a wide frequency range, further improving system accuracy.

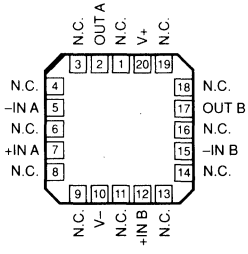
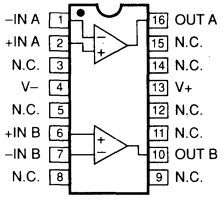
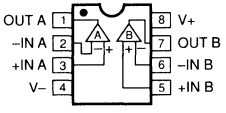
PIN CONNECTIONS



LCC (RC-Suffix)



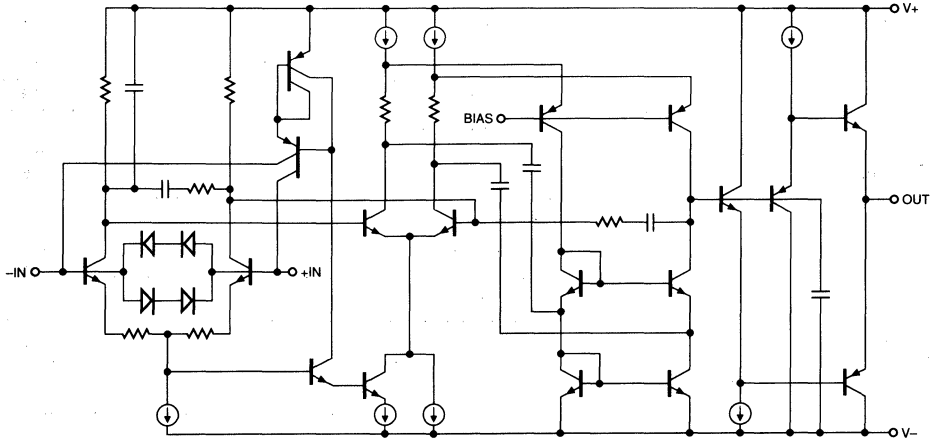
16-PIN SOL (S-Suffix)



EPOXY MINI-DIP (P-Suffix)

8-PIN HERMETIC DIP (Z-Suffix)

SIMPLIFIED SCHEMATIC (One of the two amplifiers is shown.)



This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

The OP-271 offers outstanding DC and AC matching between channels. This is especially valuable for applications such as multiple gain blocks, high-speed instrumentation and amplifiers, buffers and active filters.

The OP-271 conforms to the industry standard 8-pin dual op amp pinout. It is pin compatible with the TL072, TL082, LF412, and 1458/1558 dual op amps and can be used to significantly improve systems using these devices.

For applications requiring lower voltage noise, see the OP-270. For a quad version of the OP-271, see the OP-471.

PACKAGE TYPE	Θ_{JA} (Note 3)	Θ_{JC}	UNITS
8-Pin Hermetic DIP (Z)	134	12	°C/W
8-Pin Plastic DIP (P)	96	37	°C/W
20-Contact LCC (RC)	88	33	°C/W
8-Pin SO (S)	92	27	°C/W

NOTES:
1. Absolute maximum ratings apply to both DICE and packaged parts, unless otherwise noted.
2. The OP-271's inputs are protected by back-to-back diodes. Current limiting resistors are not used in order to achieve low noise performance. If differential voltage exceeds ±1.0V, the input current should be limited to ±25mA.
3. Θ_{JA} is specified for worst case mounting conditions, i.e., Θ_{JA} is specified for device in socket for CerDIP, P-DIP, and LCC packages; Θ_{JA} is specified for device soldered to printed circuit board for SOL package.

ELECTRICAL CHARACTERISTICS at V_S = ±15V, T_A = +25°C, unless otherwise noted.

Dual Bipolar/JFET, Audio Operational Amplifier

OP275*

FEATURES
Excellent Sonic Characteristics
Low Noise: 6 nV/√Hz
Low Distortion: 0.0006%
High Slew Rate: 22 V/μs
Wide Bandwidth: 9 MHz
Low Supply Current: 5 mA
Low Offset Voltage: 1 mV
Low Offset Current: 2 nA
Unity Gain Stable
SOIC-8 Package

APPLICATIONS
High Performance Audio
Active Filters
Fast Amplifiers
Integrators

GENERAL DESCRIPTION

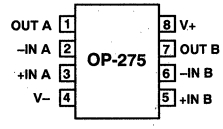
The OP-275 is the first amplifier to feature the Butler Amplifier front-end. This new front-end design combines both bipolar and JFET transistors to attain amplifiers with the accuracy and low noise performance of bipolar transistors, and the speed and sound quality of JFETs. Total Harmonic Distortion plus Noise equals previous audio amplifiers, but at much lower supply currents.

A very low 1/f corner of below 6 Hz maintains a flat noise density response. Whether noise is measured at either 30 Hz or 1 kHz, it is only 6 nV/√Hz. The JFET portion of the input stage gives the OP-275 its high slew rates to keep distortion low, even when large output swings are required, and the 22 V/μs slew rate of the OP-275 is the fastest of any standard audio amplifier. Best of all, this low noise and high speed are accomplished using less than 5 mA of supply current, lower than any standard audio amplifier.

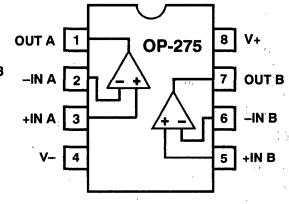
*Patent pending.

PIN CONNECTIONS

8-Lead Narrow Body SOIC (S Suffix)



8-Lead Epoxy DIP (P Suffix)



Improved dc performance is also provided with bias and offset currents greatly reduced over purely bipolar designs. Input offset voltage is guaranteed at 1 mV and is typically less than 200 μV. This allows the OP-275 to be used in many dc coupled or summing applications without the need for special selections or the added noise of additional offset adjustment circuitry.

The output is capable of driving 600 Ω loads to 10 V rms while maintaining low distortion. THD + Noise at 3 V rms is a low 0.0006%.

The OP-275 is specified over the extended industrial (−40°C to +85°C) temperature range. OP-275s are available in both plastic DIP and SOIC-8 packages. SOIC-8 packages are available in 2500 piece reels. Many audio amplifiers are not offered in SOIC-8 surface mount packages for a variety of reasons, however the OP-275 was designed so that it would offer full performance in surface mount packaging.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

Package Type	θ_{JA}[4]	θ_{JC}	Units
8-Pin Plastic DIP (P)	103	43	°C/W
8-Pin SOIC (S)	158	43	°C/W

NOTES
[1]Absolute maximum ratings apply to both DICE and packaged parts, unless otherwise noted.
[2]For supply voltages less than ±22 V, the absolute maximum input voltage is equal to the supply voltage.
[3]Shorts to either supply may destroy the device. See data sheet for full details.
[4]θ_{JA} is specified for the worst case conditions, i.e., θ_{JA} is specified for device in socket for cerdip, P-DIP, and LCC packages; θ_{JA} is specified for device soldered in circuit board for SOIC package.

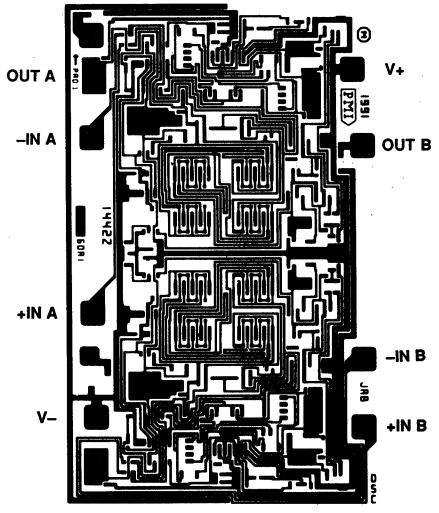
DICE CHARACTERISTICS



OP-275 Die Size 0.070 × 0.108 in. (7,560 sq. mils)

APPLICATIONS

Short Circuit Protection

The OP-275 has been designed with inherent output short circuit protection to ground.

However shorts to either supply may destroy the device when excessive voltages or currents are applied. For safe operation the output current of the OP-275 should be design limited to ±30 mA.

Total Harmonic Distortion

Total Harmonic Distortion + Noise (THD + N) of the OP-275 is well below 0.001% with any load down to 600 Ω. However, this is dependent upon the peak output swing. In Figure 1 it is seen that the THD + Noise with 3 V rms output is below 0.001%. In the following Figure 2, THD + Noise is below 0.001% for the 10 kΩ and 2 kΩ loads but increases to above 0.1% for the 600 Ω load condition. This is a result of the output swing capability of the OP-275. Notice the results in Figure 3, showing THD vs. V_{IN} (V rms). This figure shows that the THD + Noise remains very low until the output reaches 9.5 volts rms. This performance is similar to competitive products.

The output of the OP-275 is designed to maintain low harmonic distortion while driving 600 Ω loads. However, driving 600 Ω loads with very high output swings results in higher distortion if clipping occurs. A common example of this is in attempting to drive 10 V rms into any load with ±15 volt supplies. Clipping will occur and distortion will be very high.

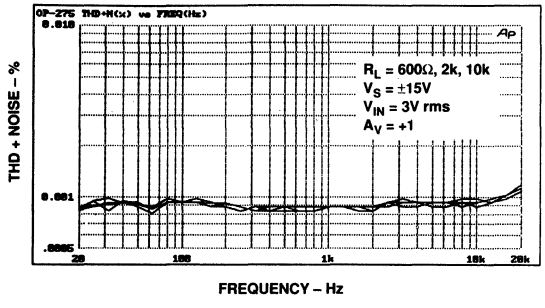


Figure 1. THD + Noise vs. Frequency vs. R_{LOAD}

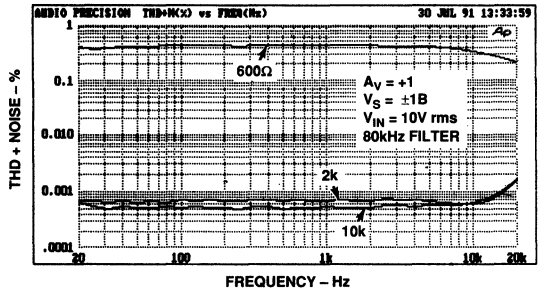

Figure 2. THD + Noise vs. R_{LOAD}; V_{IN} = 10 V rms, ±18 V Supplies

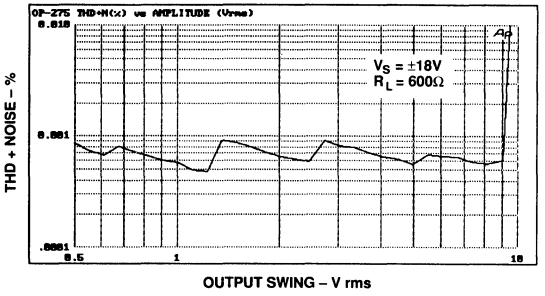

Figure 3. Headroom, THD + Noise vs. Output Amplitude (V rms); R_{LOAD} = 600 Ω, V_{SUP} = ±18 V

To attain low harmonic distortion with large output swings, supply voltages may be increased. Figure 4 shows the performance of the OP-275 driving 600 Ω loads with supply voltages varying from ±18 to ±20 volts. Notice that with ±18 volt supplies the distortion is fairly high, while with ±20 volt supplies it is a very low 0.0007%.

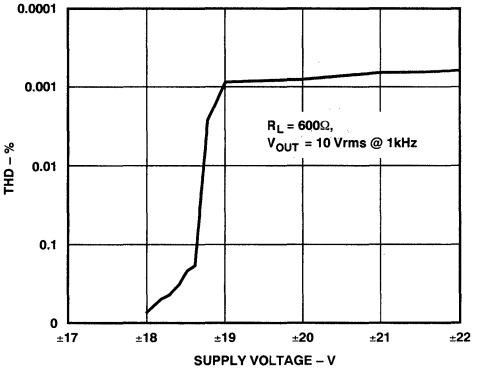

Figure 4. THD + Noise vs. Supply Voltage

Noise

The voltage noise density of the OP-275 is below 7 nV/$\sqrt{Hz}$ from 30 Hz. This enables low noise designs to have good performance throughout the full audio range. Figure 5 shows a typical OP-275 with a 1/f corner at 5.2 Hz.

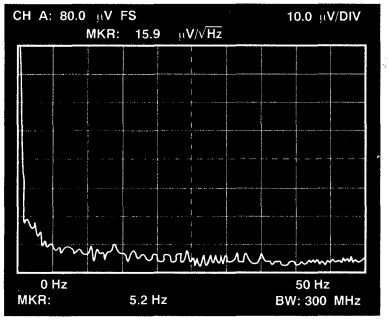

Figure 5. 1/f Noise Corner, V_s = ±15 V, A_V = 1000

Noise Testing

For audio applications the noise density is usually the most important noise parameter. For characterization the OP-275 is tested using an Audio Precision, System One. The input signal to the Audio Precision must be amplified enough to measure accurately. For the OP-275 the noise is gained by approximately 1020 using the circuit shown in Figure 6. Any readings on the Audio Precision must then be divided by the gain. In implementing this test fixture, good supply bypassing is essential.

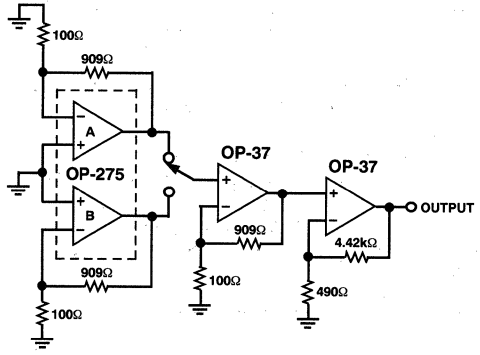

Figure 6. Noise Test Fixture

Driving Capacitive Loads

The OP-275 was designed to drive both resistive loads to 600 Ω and capacitive loads of over 1000 pF and maintain stability. While there is a degradation in bandwidth when driving capacitive loads, the designer need not worry about device stability. The graph in Figure 7 shows the 0 dB bandwidth of the OP-275 with capacitive loads from 10 pF to 1000 pF.

GENERAL DESCRIPTION

The OP279 is a dual, single-supply, high output current amplifier. It is designed for applications that require drive currents of up to 80 mA in low voltage applications.

Driving headphones directly or transformers or power transistors are applications that benefit from the OP279's high output current. The powerful output is combined with a unique input stage that maintains very low distortion with wide common-mode range even in single supply designs.

OP279s are useful amplifiers for buffering either ASICs or DACs when greater drive capability is needed than can usually be provided by CMOS outputs.

Bandwidth is 2 MHz and slew the rate is 5 V/μs, making these amplifiers well suited for single supply applications that require audio bandwidths when used in high gain configurations. Operation is guaranteed from voltages as low as 4.5 V, up to 12 V.

When using the OP279 in +5 V systems, very good audio performance can be attained. THD is below 0.01% with a 600 Ω load, and noise is a respectable 22 nV/√Hz. Supply current is less than 2 mA per amplifier.

The OP279 is available in 8-pin plastic DIP and SO-8 surface mount packages. They are specified over the extended industrial (–40°C to +85°C) temperature range.

This is a preliminary data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

Dual/Quad Low Power, High Speed JFET Operational Amplifiers

OP282/OP482

FEATURES
- High Slew Rate: 9 V/μs
- Wide Bandwidth: 4 MHz
- Low Supply Current: 250 μA/Amplifier
- Low Offset Voltage: 3 mV
- Low Bias Current: 100 pA
- Fast Settling Time
- Common-Mode Range Includes V+
- Unity Gain Stable

APPLICATIONS
- Active Filters
- Fast Amplifiers
- Integrators
- Supply Current Monitoring

GENERAL DESCRIPTION

The OP-282/OP-482 dual and quad operational amplifiers feature excellent speed at exceptionally low supply currents. Slew rate exceeds 7 V/μs with supply current under 250 μA per amplifier. These unity gain stable amplifiers have a typical gain-bandwidth of 4 MHz.

The JFET input stage of the OP-282/OP-482 insures bias current is typically a few picoamps and below 500 pA over the full temperature range. Offset voltage is under 3 mV for the dual and under 4 mV for the quad.

With a wide output swing, within 1.5 volts of each supply, low power consumption and high slew rate, the OP-282/OP-482 are ideal for battery-powered systems or power restricted applications. An input common-mode range that includes the positive supply makes the OP-282/OP-482 an excellent choice for high-side signal conditioning.

The OP-282/OP-482 are specified over the extended industrial temperature range. Both dual and quad amplifiers are available in plastic and ceramic DIP plus SOIC surface mount packages.

ANALOG DEVICES

Dual, 9 MHz Precision Operational Amplifier

OP285*

FEATURES
Low Offset Voltage: 250 μV
Low Noise: 6 nV/√Hz
Low Distortion: 0.0006%
High Slew Rate: 22 V/μs
Wide Bandwidth: 9 MHz
Low Supply Current: 5 mA
Low Offset Current: 2 nA
Unity-Gain Stable
SO-8 Package

APPLICATIONS
High Performance Audio
Active Filters
Fast Amplifiers
Integrators

GENERAL DESCRIPTION

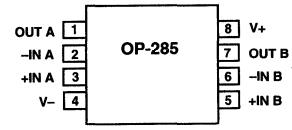
The OP-285 is a precision high speed amplifier featuring the Butler Amplifier front-end. This new front-end design combines the accuracy and low noise performance of bipolar transistors with the speed of JFETs. This yields an amplifier with high slew rates, low offset and good noise performance at low supply currents. Bias currents are also low compared to bipolar designs.

The OP-285 offers the slew rate and low power of a JFET amplifier combined with the precision, low noise and low drift of a bipolar amplifier. Input offset voltage is laser-trimmed and guaranteed less than 250 μV. This makes the OP-285 useful in dc coupled or summing applications without the need for special selections or the added noise of additional offset adjustment circuitry. Slew rates of 22 V/μs and a bandwidth of 9 MHz make the OP-285 one of the most accurate medium speed amplifiers available.

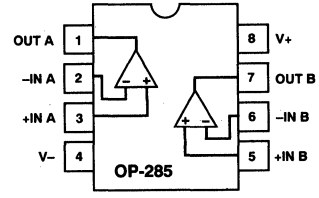
*Patents pending.

PIN CONNECTIONS

8-Lead Narrow-Body SO
(S Suffix)



8-Lead Epoxy DIP
(P Suffix)



The combination of low noise, speed and accuracy can be used to build high speed instrumentation systems. Circuits such as instrumentation amplifiers, ramp generators, bi-quad filters and dc coupled audio systems are all practical with the OP-285.

For applications that require long term stability, the OP-285 has a guaranteed maximum long term drift specification.

The OP-285 is specified over the XIND—extended industrial—(−40°C to +85°C) temperature range. OP-285s are available in 8-pin plastic DIP and SOIC-8 surface mount packages.

APPLICATIONS

Short Circuit Protection

The OP-285 has been designed with inherent short circuit protection to ground. An internal 30 Ω resistor, in series with the output, limits the output current at room temperature to $I_{SC}+$ = 40 mA and $I_{SC}-$ = −90 mA, typically, with ±15 V supplies.

However, shorts to either supply may destroy the device when excessive voltages or current are applied. If it is possible for a user to short an output to a supply, for safe operation, the output current of the OP-285 should be design-limited to ±30 mA, as shown in Figure 1.

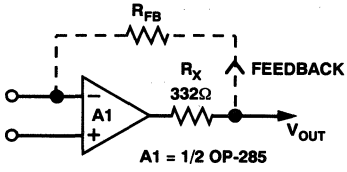

Figure 1. Recommended Output Short Circuit Protection

Input Over Current Protection

The maximum input differential voltage that can be applied to the OP-285 is determined by a pair of internal Zener diodes connected across the inputs. They limit the maximum differential input voltage to ±7.5 V. This is to prevent emitter-base junction breakdown from occurring in the input stage of the OP-285 when very large differential voltages are applied. However, in order to preserve the OP-285's low input noise voltage, internal resistance in series with the inputs were not used to limit the current in the clamp diodes. In small-signal applications, this is not an issue; however, in industrial applications, where large differential voltages can be inadvertently applied to the device, large transient currents can be made to flow through these diodes. The diodes have been designed to carry a current of ±8 mA; and, in applications where the OP-285's differential voltage were to exceed ±7.5 V, the resistor values shown in Figure 2 safely limit the diode current to ±8 mA.

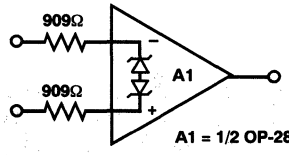

Figure 2. OP-285 Input Over Current Protection

Output Voltage Phase Reversal

Since the OP-285's input stage combines bipolar transistors for low noise and p-channel JFETs for high speed performance, the output voltage of the OP-285 may exhibit phase reversal if either of its inputs exceed its negative common-mode input voltage. This might occur in very severe industrial applications where a sensor, or system, fault might apply very large voltages on the inputs of the OP-285. Even though the input voltage range of the OP-285 is ±10.5 V, an input voltage of approximately −13.5 V will cause output voltage phase reversal. In inverting amplifier configurations, the OP-285's internal 7.5 V input clamping diodes will prevent phase reversal; however, they will not prevent this effect from occurring in noninverting applications. For these applications, the fix is a simple one and is illustrated in Figure 3. A 3.92 kΩ resistor in series with the noninverting input of the OP-285 cures the problem.

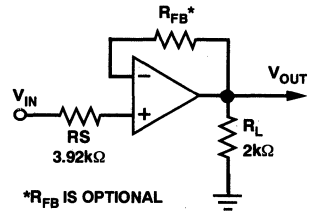

Figure 3. Output Voltage Phase Reversal Fix

Overload, or Overdrive, Recovery

Overload, or overdrive, recovery time of an operational amplifier is the time required for the output voltage to recover to a rated output voltage from a saturated condition. This recovery time is important in applications where the amplifier must recover quickly after a large abnormal transient event. The circuit shown in Figure 4 was used to evaluate the OP-285's overload recovery time. The OP-285 takes approximately 1.2 μs to recover to V_{OUT} = +10 V and approximately 1.5 μs to recover to V_{OUT} = −10 V.

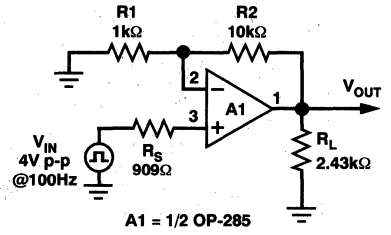

Figure 4. Overload Recovery Time Test Circuit

Driving the Analog Input of an A/D Converter

Settling characteristics of operational amplifiers also include the amplifier's ability to recover, i.e., settle, from a transient output current load condition. When driving the input of an A/D converter, especially successive-approximation converters, the amplifier must maintain a constant output voltage under dynamically changing load current conditions. In these types of converters, the comparison point is usually diode clamped, but it may deviate several hundred millivolts resulting in high frequency modulation of the A/D input current. Amplifiers that exhibit high closed-loop output impedances and/or low unity-gain crossover frequencies recover very slowly from output load current transients. This slow recovery leads to linearity errors or missing codes because of errors in the instantaneous input voltage. Therefore, the amplifier chosen for this type of application should exhibit low output impedance and high unity-gain bandwidth so that its output has had a chance to settle to its nominal value before the converter makes its comparison.

The circuit in Figure 5 illustrates a settling measurement circuit for evaluating the recovery time of an amplifier from an output load current transient. The amplifier is configured as a follower with a very high speed current generator connected to its output. In this test, a 1 mA transient current was used. As shown in Figure 6, the OP-285 exhibits an extremely fast recovery time of 139 ns to 0.01%. Because of its high gain-bandwidth product,

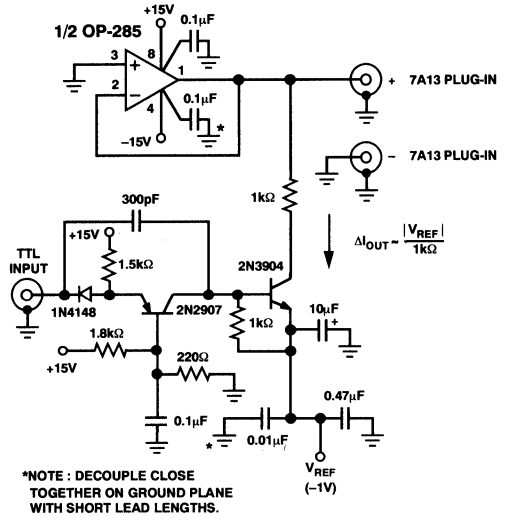

Figure 5. Transient Output Load Current Test Fixture

high open-loop gain, and low output impedance, the OP-285 is ideally suited to drive high speed A/D converters.

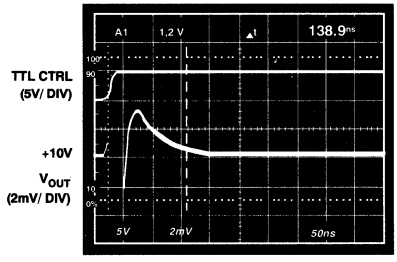

Figure 6. OP-285's Output Load Current Recovery Time

Measuring Settling Time

The design of OP-285 combines high slew rate and wide gain-bandwidth product to produce a fast-settling (t_S < 1 μs) amplifier for 8- and 12-bit applications. The test circuit designed to measure the settling time of the OP-285 is shown in Figure 7. This test method has advantages over false-sum node techniques in that the actual output of the amplifier is measured, instead of an error voltage at the sum node. Common-mode settling effects are exercised in this circuit in addition to the slew rate and bandwidth effects measured by the false-sum-node method. Of course, a reasonably flat-top pulse is required as the stimulus.

The output waveform of the OP-285 under test is clamped by Schottky diodes and buffered the JFET source follower. The signal is amplified by a factor of ten by the OP-260 and then Schottky-clamped at the output to prevent overloading the oscilloscope's input amplifier. The OP-41 is configured as a fast integrator which provides overall dc offset nulling.

High Speed Operation

As with most high speed amplifiers, care should be taken with supply decoupling, lead dress, and component placement. Recommended circuit configurations for inverting and noninverting applications are shown in Figures 8 and Figure 9.

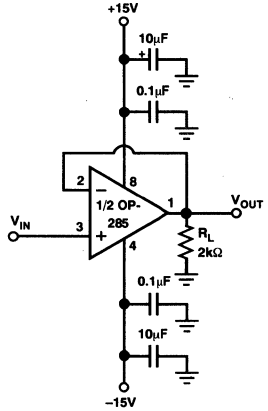

Figure 8. Unity Gain Follower

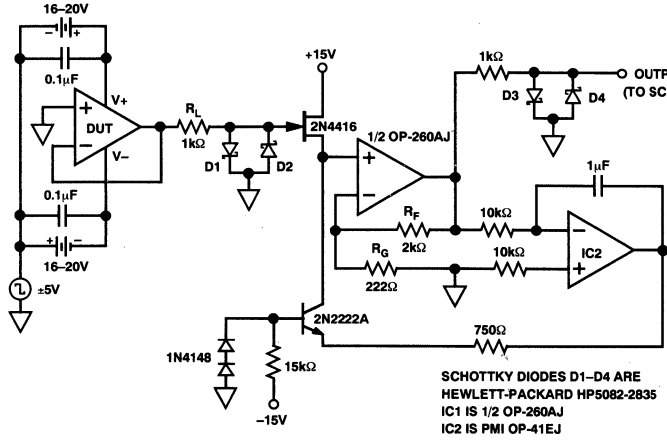

Figure 7. OP-285's Settling Time Test Fixture

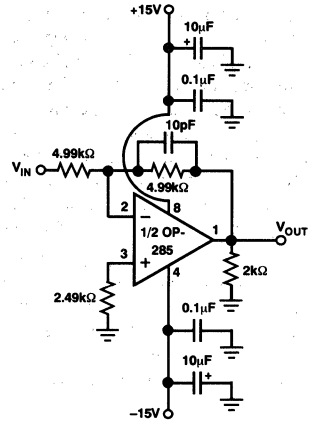

Figure 9. Unity Gain Inverter

In inverting and noninverting applications, the feedback resistance forms a pole with the source resistance and capacitance (R_S and C_S) and the OP-285's input capacitance (C_{IN}), as shown in Figure 10. With R_S and R_F in the kilohm range, this pole can create excess phase shift and even oscillation. A small capacitor, C_{FB}, in parallel with R_{FB} eliminates this problem. By setting R_S (C_S + C_{IN}) = $R_{FB}C_{FB}$, the effect of the feedback pole is completely removed.

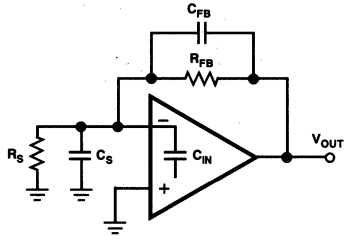

Figure 10. Compensating the Feedback Pole

High Speed, Low Noise Differential Line Driver

The circuit of Figure 11 is a unique line driver widely used in industrial applications. With ±18 V supplies, the line driver can deliver a differential signal of 30 V p-p into a 2.5 kΩ load. The high slew rate and wide bandwidth of the OP-285 combine to yield a full power bandwidth of 130 kHz while the low noise front end produces a referred-to-input noise voltage spectral density of 10 nV/$\sqrt{Hz}$. The design is a transformerless, balanced transmission system where output common-mode rejection of noise is of paramount importance. Like the transformer-based design, either output can be shorted to ground for unbalanced line driver applications without changing the circuit gain of 1. Other circuit gains can be set according to the equation in the diagram. This allows the design to be easily set to noninverting, inverting, or differential operation.

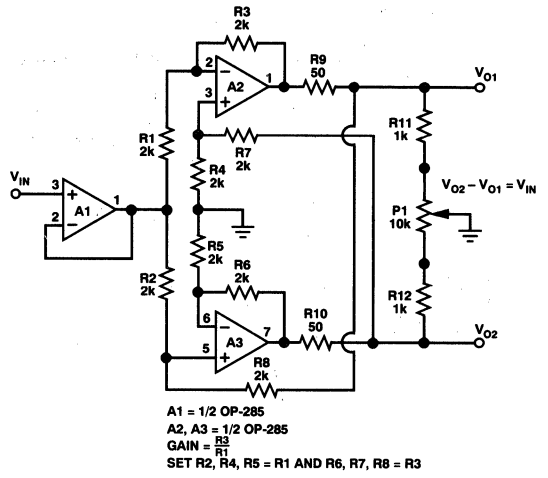

Figure 11. High Speed, Low Noise Differential Line Driver

Low Phase Error Amplifier

The simple amplifier configuration of Figure 12 utilizes the OP-285 and a few resistors to reduce phase error substantially over a wide frequency range when compared to conventional amplifier designs. This technique relies on the matched frequency characteristics of the two amplifiers in the OP-285. Each amplifier in the circuit has the same feedback network which produces a circuit gain of 10. Since the two amplifiers are set to the same gain and are matched due to the monolithic construction of the OP-285, they will exhibit identical frequency response. Recall from feedback theory that a pole of a feedback network becomes a zero in the loop gain response. By using this technique, the dominant pole of the amplifier in the feedback loop compensates for the dominant pole of the main amplifier,

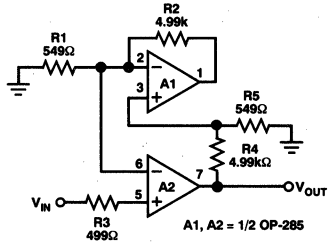

Figure 12. Active Feedback Allows Cancellation of A2's Dominant Pole by A1 Which Reduces the Phase Shift Significantly.

thereby reducing phase error dramatically. This is shown in Figure 13 where the 10× composite amplifier's phase response exhibits less than 1.5° phase shift through 500 kHz. On the other hand, the single gain stage amplifier exhibits 25 degrees of phase shift over the same frequency range. An additional benefit of the low phase error configuration is constant group delay, by virtue of constant phase shift at all frequencies below 500 kHz. Although this technique is valid for minimum circuit gains of 10, actual closed-loop magnitude response must be optimized for the amplifier chosen.

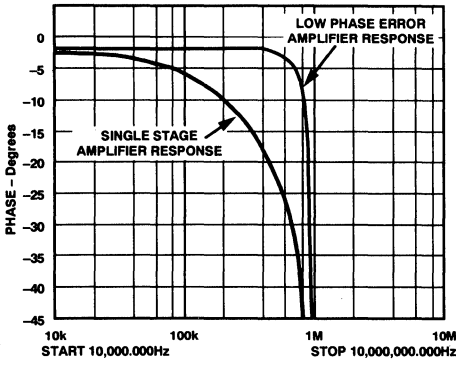

Figure 13. Phase Error Comparison

For a more detailed treatment on the design of low phase error amplifiers, please see Application Note AN-107.

Fast Current Pump

A fast, ±30 mA current source, illustrated in Figure 14, takes advantage of the OP-285's speed and high output current drive. This is a variation of the Howland current source where a second amplifier, A2, is used to increase load current accuracy and output voltage compliance. With supply voltages of ±15 V, the output voltage compliance of the current pump is ±8 V. To keep the output resistance in the MΩ range requires that 0.1% or better resistors be used in the circuit. The gain of the current pump can be easily changed according to the equations shown in the diagram.

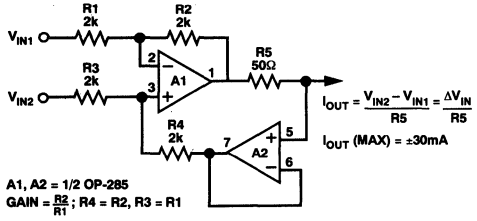

Figure 14. A Fast Current Pump

A Low Noise, High Speed Instrumentation Amplifier

A high speed, low noise instrumentation amplifier, constructed with a single OP-285, is illustrated in Figure 15. The circuit exhibits less than 1.2 μV p-p noise (RTI) in the 0.1 Hz to 10 Hz band and an input noise voltage spectral density of 9 nV/$\sqrt{Hz}$ (1 kHz) at a gain of 1000. The gain of the amplifier is easily set by R_G according to the formula:

$$\frac{V_{OUT}}{V_{IN}} = \frac{9.98\ k\Omega}{R_G} + 2$$

The advantages of a two op amp instrumentation amplifier based on a dual op amp is that the errors in the individual amplifiers tend to cancel one another. For example, the circuit's input offset voltage is determined by the input offset voltage matching of the OP-285, which is typically less than 250 μV.

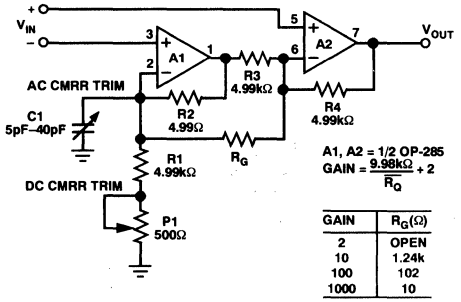

Figure 15. A High Speed Instrumentation Amplifier

Common-mode rejection of the circuit is limited by the matching of resistors R1 to R4. For good common-mode rejection, these resistors ought to be matched to better than 1%. The circuit was constructed with 1% resistors and included potentiometer P1 for trimming the DC CMRR and a capacitor C1 for trimming the AC CMRR. With these two trims, the circuit's common-mode rejection was better than 95 dB at 60 Hz and better than 65 dB at 10 kHz. For the best common-mode rejection performance, use a matched (better than 0.1%) thin-film resistor network for R1 through R4 and use the variable capacitor to optimize the circuit's AC CMR.

The instrumentation amplifier exhibits very wide small- and large-signal bandwidths regardless of the gain setting, as shown in the table. Because of its low noise, wide gain-bandwidth product, and high slew rate, the OP-285 is ideally suited for high speed signal conditioning applications.

Circuit Gain	R_G (Ω)	Circuit Bandwidth V_{OUT} = 100 mV p-p	Circuit Bandwidth V_{OUT} = 20 V p-p
2	Open	5 MHz	780 kHz
10	1.24 k	1 MHz	460 kHz
100	102	90 kHz	85 kHz
1000	10	10 kHz	10 kHz

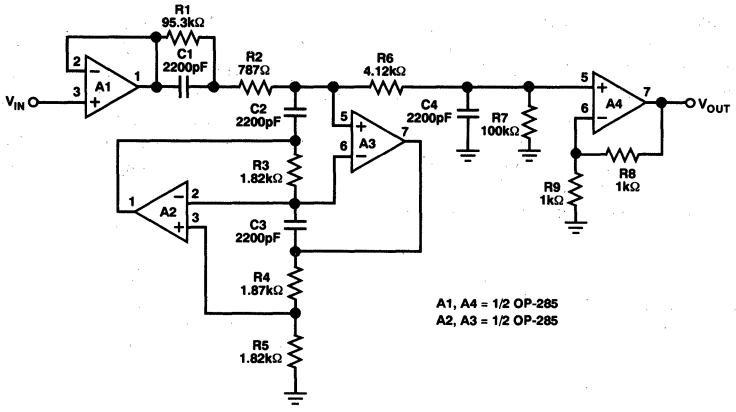

Figure 16. A 3-Pole, 40 kHz Low-Pass Filter

A 3-Pole, 40 kHz Low-Pass Filter

The closely matched and uniform ac characteristics of the OP-285 make it ideal for use in GIC (Generalized Impedance Converter) and FDNR (Frequency-Dependent Negative Resistor) filter applications. The circuit in Figure 16 illustrates a linear-phase, 3-pole, 40 kHz low-pass filter using an OP-285 as an inductance simulator (gyrator). The circuit uses one OP-285 (A2 and A3) for the FDNR and one OP-285 (A1 and A4) as an input buffer and bias current source for A3. Amplifier A4 is configured in a gain of 2 to set the pass band magnitude response to 0 dB. The benefits of this filter topology over classical approaches are that the op amp used in the FDNR is not in the signal path and that the filter's performance is relatively insensitive to component variations. Also, the configuration is such that large signal levels can be handled without overloading any of the filter's internal nodes. As shown in Figure 17, the OP-285's symmetric slew rate and low distortion produce a clean, well-behaved transient response.

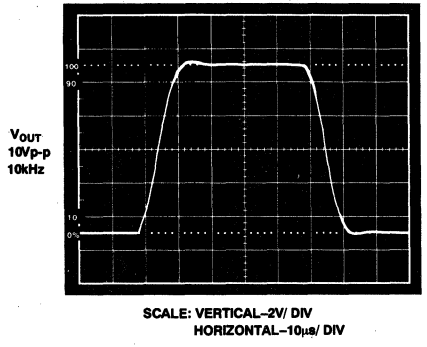

Figure 17. Low-Pass Filter Transient Response

Driving Capacitive Loads

The OP-285 was designed to drive both resistive loads to 600 Ω and capacitive loads of over 1000 pF and maintain stability. While there is a degradation in bandwidth when driving capacitive loads, the designer need not worry about device stability. The graph in Figure 18 shows the 0 dB bandwidth of the OP-285 with capacitive loads from 10 pF to 1000 pF.

GENERAL DESCRIPTION

The OP-290 is a high performance micropower dual op amp that operates from a single supply of +1.6V to +36V or from dual supplies of ±0.8V to ±18V. Input voltage range includes the negative rail allowing the OP-290 to accommodate input signals down to ground in single supply operation. The OP-290's output swing also includes ground when operating from a single supply, enabling "zero-in, zero-out" operation.

The OP-290 draws less than 20μA of quiescent supply current per amplifier, while able to deliver over 5mA of output current to a load. Input offset voltage is below 200μV eliminating the need for external nulling. Gain exceeds 700,000 and common-mode rejection is better than 100dB. The power

GENERAL DESCRIPTION *Continued*

supply rejection ratio of under 5.6μV/V minimizes offset voltage changes experienced in battery powered systems.

The low offset voltage and high gain offered by the OP-290 bring precision performance to micropower applications. The minimal voltage and current requirements of the OP-290 suit it for battery and solar powered applications, such as portable instruments, remote sensors, and satellites. For a single op amp, see the OP-90; for a quad, see the OP-490.

Micropower Single-Supply Rail-to-Rail Input & Output Op Amps

OP291/OP491

FEATURES
Single-Supply Operation: 2.7 V to 12 V
Wide Input Voltage Range
Rail-to-Rail Output Swing
Low Supply Current: 300 μA/Amp
Wide Bandwidth: 3 MHz
Slew Rate: 0.5 V/μs
Low Offset Voltage: 700 μV
No Phase Reversal
Drives Capacitive Loads

APPLICATIONS
Industrial Process Control
Battery Powered Instrumentation
Power Supply Control and Protection
Telecom
Remote Sensors
Low Voltage Strain Gage Amplifiers
DAC Output Amplifier

GENERAL DESCRIPTION

The OP291 and OP491 are dual and quad micropower single-supply, 3 MHz bandwidth amplifiers featuring rail-to-rail inputs and outputs. The OP291 and OP491 are guaranteed to operate from a 3 volt single supply as well as ±5 volt dual supplies.

Fabricated on Analog Devices' CBCMOS process, the OP291/OP491 have a unique input stage that allows the input voltage to safely extend 10 volts beyond either supply without any phase inversion or latch-up. The output voltage swings to within millivolts of the supplies and continues to sink or source current all the way to the supplies.

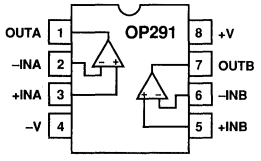
Applications for these amplifiers include portable telecom equipment, power supply control and protection, and interface for transducers with wide output ranges. Sensors requiring a rail-to-rail input amplifier include Hall effect, piezo electric, and resistive transducers.

The ability to swing rail-to-rail at both the input and output enables designers to build multistage filters in single-supply systems and maintain high signal-to-noise ratios.

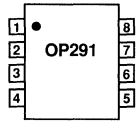
The OP291/OP491 are specified over the extended industrial (–40°C to +125°C) temperature range. The OP291 dual amplifiers are available in 8-pin plastic DIPs and SO surface mount packages. The OP491 quad is available in 14-pin DIPs and 14-pin SO packages.

PIN CONFIGURATIONS

8-Lead Epoxy DIP (P Suffix)



8-Lead Narrow-Body SO (S Suffix)



14-Lead Epoxy DIP (P Suffix)

FUNCTIONAL DESCRIPTION

The OP291 and OP491 are single supply, micropower amplifiers featuring rail-to-rail inputs and outputs. In order to achieve wide input and output ranges, these amplifiers employ unique input and output stages. As the simplified schematic shows (Figure 55), the input stage is actually comprised of two differential pairs, a PNP pair and an NPN pair. These two stages do not actually work in parallel. Instead, only one or the other stage is on for any given input signal level. The PNP stage (transistors Q1 and Q2) is required to ensure that the amplifier remains in the linear region when the input voltage approaches and reaches the negative rail. On the other hand, the NPN stage (transistors Q5 and Q6) is needed for input voltages up to and including the positive rail.

For the majority of the input common-mode range, the PNP stage is active, as is evidenced by examining the graph of Input Bias Current vs. Common-Mode Voltage. Notice that the bias current switches direction at approximately 1.2 volts to 1.3 volts below the positive rail. At voltages below this, the bias current flows out of the OP291, indicating a PNP input stage. Above this voltage, however, the bias current enters the device, revealing the NPN stage. The actual mechanism within the amplifier for switching between the input stages is comprised of the transistors Q3, Q4, and Q7. As the input common-mode voltage increases, the emitters of Q1 and Q2 follow that voltage plus a diode drop. Eventually the emitters of Q1 and Q2 are high enough to turn Q3 on. This diverts the 8 μA of tail current away from the PNP input stage, turning it off. Instead, the current is mirrored through Q4 and Q7 to activate the NPN input stage.

Notice that the input stage includes 5 kΩ series resistors and differential diodes, a common practice in bipolar amplifiers to protect the input transistors from large differential voltages. These diodes will turn on whenever the differential voltage exceeds approximately 0.6 V. In this condition, current will flow between the input pins, limited only by the two 5 kΩ resistors. Being aware of this characteristic is important in circuits where the amplifier may be operated open-loop, such as a comparator. Evaluate each circuit carefully to make sure that the increase in current does not affect the performance.

The output stage of the OP291/OP491 uses a PNP and an NPN transistor as do most output stages; however, the output transistors, Q32 and Q33, are actually connected with their collectors to the output pin to achieve the rail-to-rail output swing. As the output voltage approaches either the positive or negative rail, these transistors begin to saturate. Thus, the final limit on output voltage is the saturation voltage of these transistors, which is about 50 mV. The output stage does have inherent gain arising from the collectors and any external load impedance. Because of this, the open-loop gain of the amplifier is dependent on the load resistance.

Input Overvoltage Protection

As with any semiconductor device, whenever the condition exists for the input to exceed either supply voltage, attention needs to be paid to the input overvoltage characteristic. When an overvoltage occurs, the amplifier could be damaged depending on the voltage level and the magnitude of the fault current. Figure 56 shows the characteristic for the OP291 and OP491. This graph was generated with the power supplies at ground and a curve tracer connected to the input. As can be seen, when the input voltage exceeds either supply by more than 0.6 V, internal pn-junctions energize allowing current to flow from the input to the supplies. As described above, the OP291/OP491 does have 5 kΩ resistors in series with each input, which helps limit the current. Calculating the slope of the current versus voltage in the graph confirms the 5 kΩ resistor.

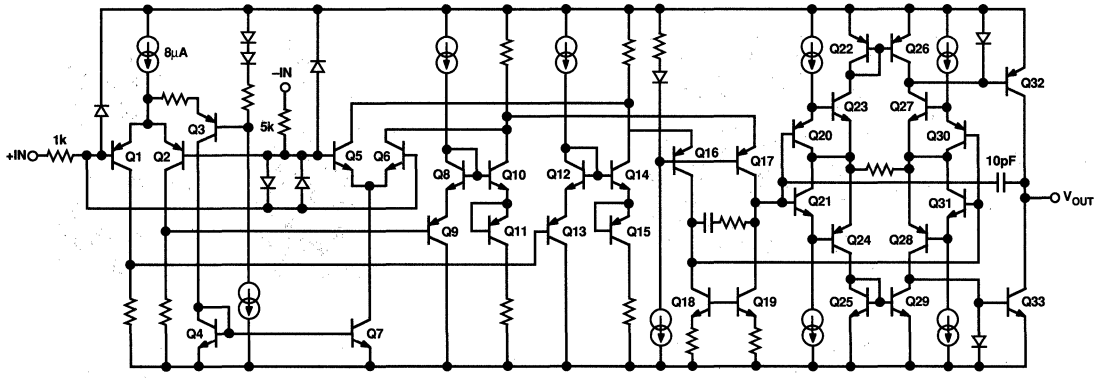

Figure 55. OP291/OP491 Simplified Schematic

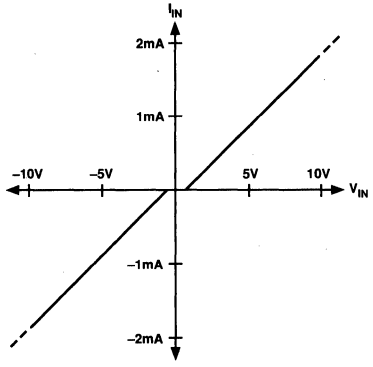

Figure 56. Input Overvoltage Characteristics

This input current is not inherently damaging to the device as long as it is limited to 5 mA or less. In the case shown, for an input of 10 V over the supply, the current is limited to 1.8 mA. If the voltage is large enough to cause more than 5 mA of current to flow, then an external series resistor should be added. The size of this resistor is calculated by dividing the maximum overvoltage by 5 mA and subtracting the internal 5 kΩ resistor. For example, if the input voltage could reach 100 V, the external resistor should be (100 V/5 mA) –5 k = 15 kΩ. This resistance should be placed in series with either or both inputs if they are subjected to the overvoltages. For more information on general overvoltage characteristics of amplifiers refer to the *1993 System Applications Guide*, available from the Analog Devices Literature Center.

Output Voltage Phase Reversal

Some operational amplifiers designed for single-supply operation exhibit an output voltage phase reversal when their inputs are driven beyond their useful common-mode range. Typically for single-supply bipolar op amps, the negative supply determines the lower limit of their common-mode range. With these devices, external clamping diodes, with the anode connected to ground and the cathode to the inputs, prevent input signal excursions from exceeding the device's negative supply (i.e., GND), preventing a condition which could cause the output voltage to change phase. JFET-input amplifiers may also exhibit phase reversal, and, if so, a series input resistor is usually required to prevent it.

The OP291/OP491 is free from reasonable input voltage range restrictions due to its novel input structure. In fact, the input signal can exceed the supply voltage by a significant amount without causing damage to the device. As illustrated in Figure 57, the OP291/OP491 can safely handle a 20 V p-p input signal on ±5 V supplies without exhibiting any sign of output voltage phase reversal or other anomalous behavior. Thus no external clamping diodes are required.

Overdrive Recovery

The overdrive recovery time of an operational amplifier is the time required for the output voltage to recover to its linear region from a saturated condition. This recovery time is important in applications where the amplifier must recover quickly after a large transient event, such as a comparator. The circuit shown in Figure 58 was used to evaluate the OP291/OP491's overload recovery time. The OP291/OP491 takes approximately 8 µs to recover from positive saturation and approximately 6.5 µs to recover from negative saturation.

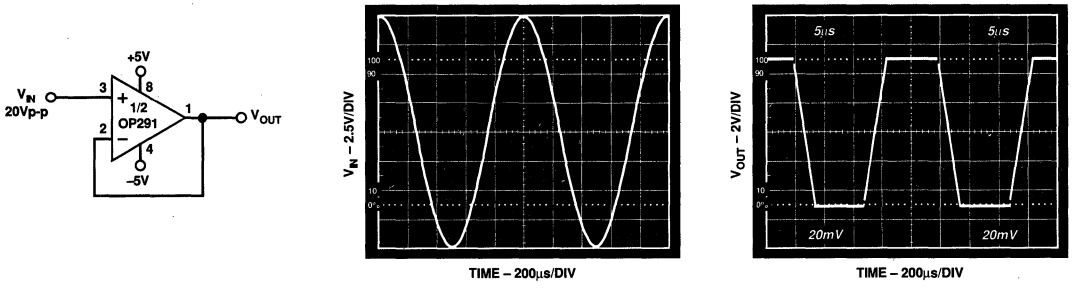

Figure 57. OP291/OP491 Output Voltage Phase Reversal Behavior

APPLICATIONS

Single +3 V Supply, Instrumentation Amplifier

The OP291's low supply current and low voltage operation make it ideal for battery powered applications such as the instrumentation amplifier shown in Figure 59. The circuit utilizes the classic two op amp instrumentation amplifier topology, with four resistors to set the gain. The equation is simply that of a noninverting amplifier as shown in the figure. The two resistors labeled R1 should be closely matched to each other as well as both resistors labeled R2 to ensure good common-mode rejection performance. Resistor networks ensure the closest matching as well as matched drifts for good temperature stability. Capacitor C1 is included to limit the bandwidth and, therefore, the noise in sensitive applications. The value of this capacitor should be adjusted depending on the desired closed-loop bandwidth of the instrumentation amplifier. The RC combination creates a pole at a frequency equal to $1/(2\pi \times R1C1)$. If AC-CMRR is critical, than a matched capacitor to C1 should be included across the second resistor labeled R1.

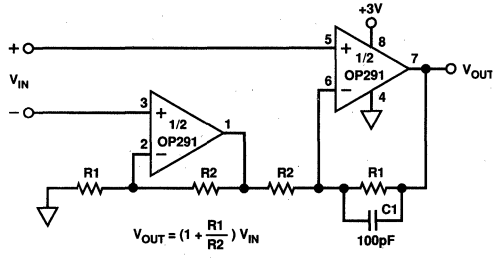

Figure 59. Single +3 V Supply Instrumentation Amplifier

Because the OP291 accepts rail-to-rail inputs, the input common-mode range includes both ground and the positive supply of 3 V. Furthermore, the rail-to-rail output range ensures the widest signal range possible and maximizes the dynamic range of the system. Also, with its low supply current of 300 µA/device, this circuit consumes a quiescent current of only 600 µA, yet still exhibits a gain bandwidth of 3 MHz.

A question may arise about other instrumentation amplifier topologies for single supply applications. For example, a variation on this topology adds a fifth resistor between the two inverting inputs of the op amps for gain setting. While that topology works well in dual supply applications, it is inherently not appropriate for single supply circuits. The same could be said for the traditional three op amp instrumentation amplifier. In both cases, the circuits simply will not work in single supply situations unless a false ground between the supplies is created.

Single Supply RTD Amplifier

The circuit in Figure 60. uses three op amps of the OP491 to develop a bridge configuration for an RTD amplifier that operates from a single +5 V supply. The circuit takes advantage of the OP491's wide output swing range to generate a high bridge excitation voltage of 3.9 V. In fact, because of the rail-to-rail output swing, this circuit will work with supplies as low as 4.0 V. Amplifier A1 servos the bridge to create a constant excitation current in conjunction with the AD589, a 1.235 V precision reference. The op amp maintains the reference voltage across the parallel combination of the 6.19 kΩ and 2.55 MΩ resistor, which generates a 200 µA current source. This current splits evenly and flows through both halves of the bridge. Thus, 100 µA flows through the RTD to generate an output voltage based on its resistance. A 3-wire RTD is used to balance the line resistance in both 100 Ω legs of the bridge to improve accuracy.

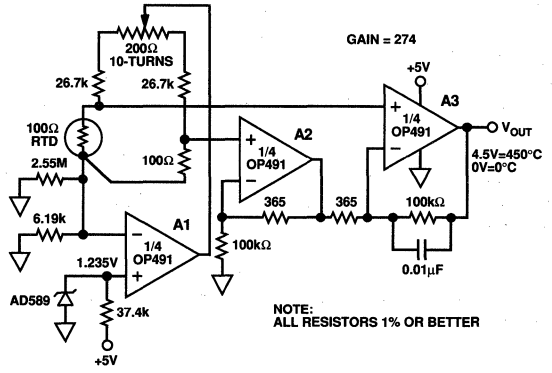

Figure 60. Single Supply RTD Amplifier

Amplifiers A2 and A3 are configured in the two op amp IA discussed above. Their resistors are chosen to produce a gain of 274, such that each 1°C increase in temperature results in a 10 mV change in the output voltage, for ease of measurement. A 0.01 µF capacitor is included in parallel with the 100 kΩ resistor on amplifier A3 to filter out any unwanted noise from this high gain circuit. This particular RC combination creates a pole at 1.6 kHz.

A +2.5 V Reference from a +3 V Supply

In many single-supply applications, the need for a 2.5 V reference often arises. Many commercially available monolithic 2.5 V references require at least a minimum operating supply voltage of 4 V. The problem is exacerbated when the minimum operating system supply voltage is + 3 V. The circuit illustrated in Figure 61 is an example of a +2.5 V that operates from a single +3 V supply. The circuit takes advantage of the OP291's rail-to-rail input and output voltage ranges to amplify an AD589's 1.235 V output to +2.5 V. The OP291's low TCV_{OS} of 1 µV/°C helps to maintain an output voltage temperature coefficient of less than 200 ppm/°C. The circuit's overall temperature coefficient is dominated by R2 and R3's temperature coefficient. Lower tempco resistors are recommended. The entire circuit draws less than 420 µA from a +3 V supply at 25°C.

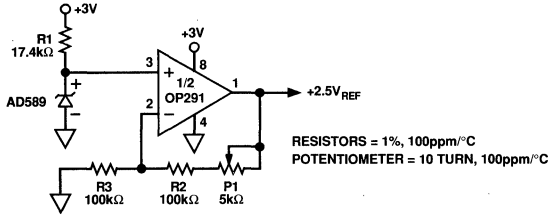

Figure 61. A +2.5 V Reference that Operates on a Single +3 V Supply

+5 V Only, 12-Bit DAC Swings Rail-to-Rail

The OP291 or OP491 are ideal for use with a CMOS DAC to generate a digitally controlled voltage with a wide output range. Figure 62 shows the DAC8043 used in conjunction with the AD589 to generate a voltage output from 0 V to 1.23 V The DAC is actually operated in "voltage switching" mode where the reference is connected to the current output, I_{OUT}, and the output voltage is taken from the V_{REF} pin. This topology is inherently noninverting as opposed to the classic current output mode, which is inverting and, therefore, unsuitable for single supply.

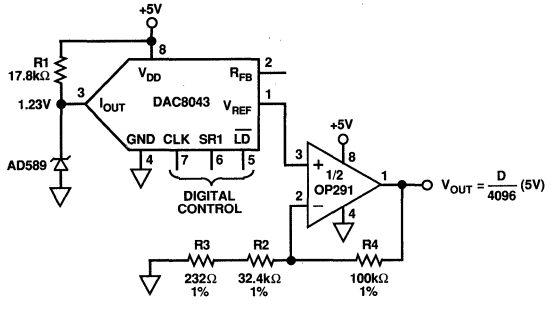

Figure 62. +5 V Only, 12-Bit DAC Swings Rail-to-Rail

The OP291 serves two functions. First, it is required to buffer the high output impedance of the DAC's V_{REF} pin, which is on the order of 10 kΩ. The op amp provides a low impedance output to drive any following circuitry. Secondly, the op amp amplifies the output signal to provide a rail-to-rail output swing. In this particular case, the gain is set to 4.1 to generate a 5.0 V output when the DAC is at full scale. If other output voltage ranges are needed, such as 0 to 4.095, the gain can easily be adjusted by altering the value of the resistors.

A High Side Current Monitor

In the design of power supply control circuits, a great deal of design effort is focused on ensuring a pass transistor's long-term reliability over a wide range of load current conditions. As a result, monitoring and limiting device power dissipation is of prime importance in these designs. The circuit illustrated in Figure 63 is an example of a +5 V, single-supply high side current monitor that can be incorporated into the design of a voltage regulator with fold-back current limiting or a high current power supply with crowbar protection. This design uses an OP291's rail-to-rail input voltage range to sense the voltage drop across a 0.1 Ω current shunt. A p-channel MOSFET used as the feedback element in the circuit converts the op amp's differential input voltage into a current. This current is then applied to R2 to generate a voltage that is a linear representation of the load current. The transfer equation for the current monitor is given by:

$$Monitor\ Output = R2 \times \left(\frac{R_{SENSE}}{R1}\right) \times I_L$$

For the element values shown, the Monitor Output's transfer characteristic is 2.5 V/A.

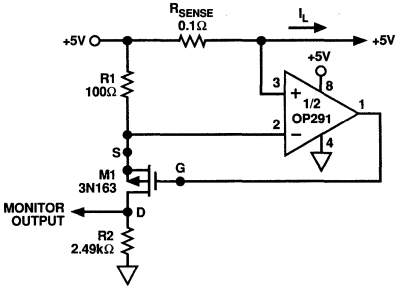

Figure 63. A High-Side Load Current Monitor

A +3 V, Cold Junction Compensated Thermocouple Amplifier
The OP291's low supply operation makes it ideal for +3 V battery powered applications such as the thermocouple amplifier shown in Figure 64. The K-type thermocouple terminates in an isothermal block where the junctions' ambient temperature is continuously monitored using a simple 1N914 diode. The diode corrects the thermal EMF generated in the junctions by feeding a small voltage, scaled by the 1.5 MΩ and 475 Ω resistors, to the op amp.

To calibrate this circuit, immerse the thermocouple measuring junction in a 0°C ice bath, and adjust the 500 Ω pot to zero volts out. Next, immerse the thermocouple in a 250°C temperature bath or oven and adjust the Scale Adjust pot for an output voltage of 2.50 V. Within this temperature range, the K-type thermocouple is accurate to within ±3°C without linearization.

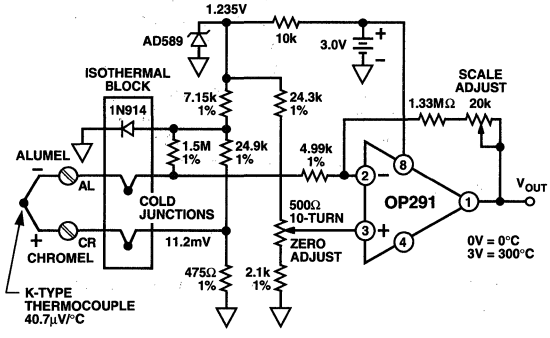

Figure 64. A 3 V, Cold Junction Compensated Thermocouple Amplifier

Single Supply, Direct Access Arrangement for Modems
An important building block in modems is the telephone line interface. In the circuit shown in Figure 65, a direct access arrangement is utilized for transmitting and receiving data from the telephone line. Amplifier A1 is the receiving amplifier, and amplifiers A2 and A3 are the transmitters. The forth amplifier, A4, generates a pseudo ground half way between the supply voltage and ground. This pseudo ground is needed for the ac coupled bipolar input signals.

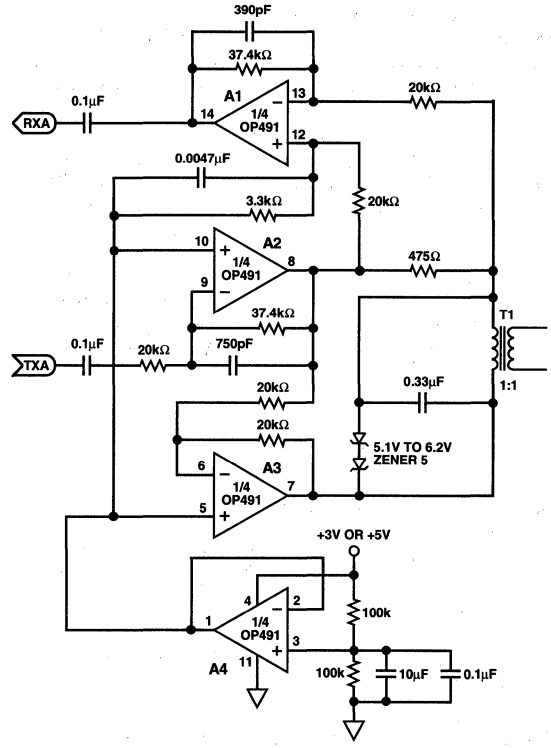

Figure 65. Single Supply Direct Access Arrangement for Modems

The transmit signal, TXA, is inverted by A2 and then re-inverted by A3 to provide a differential drive to the transformer, where each amplifier supplies half the drive signal. This is needed because of the smaller swings associated with a single supply as opposed to a dual supply. Amplifier A1 provides some gain for the received signal, and it also removes the transmit signal present at the transformer from the receive signal. To do this, the drive signal from A2 is also fed to the noninverting input of A1 to cancel the transmit signal from the transformer. The OP491's bandwidth of 3 MHz and rail-to-rail output swings ensures that it can provide the largest possible drive to the transformer at the frequency of transmission.

A +3 V, 50 Hz/60 Hz Active Notch Filter with False Ground

To process ac signals in a single-supply system, it is often best to use a false-ground biasing scheme. A circuit that uses this approach is illustrated in Figure 66. In this circuit, a false-ground circuit biases an active notch filter used to reject 50 Hz/60 Hz power line interference in portable patient monitoring equipment. Notch filters are quite commonly used to reject power line frequency interference which oftentimes obscures low frequency physiological signals, such as heart rates, blood pressure readings, EEGs, EKGs, et cetera. This notch filter effectively squelches 60 Hz pickup at a filter Q of 0.75. Substituting 3.16 kΩ resistors for the 2.67 kΩ resistors in the twin-T section (R1 through R5) configures the active filter to reject 50 Hz interference.

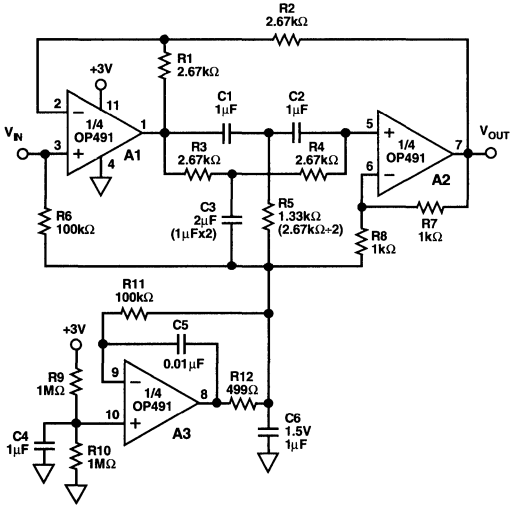

Figure 66. A +3 V Single-Supply, 50 Hz/60 Hz Active Notch Filter with False Ground

Amplifier A3 is the heart of the false-ground bias circuit. It simply buffers the voltage developed by R9 and R10 and is the reference for the active notch filter. Since the OP491 exhibits a rail-to-rail input common-mode range, R9 and R10 are chosen to split the +3 V supply symmetrically. An in-the-loop compensation scheme is used around the OP491 that allows the op amp to drive C6, a 1 μF capacitor, without oscillation. C6 maintains a low impedance ac ground over the operating frequency range of the filter.

The filter section uses a pair of OP491s in a twin-T configuration whose frequency selectivity is very sensitive to the relative matching of the capacitors and resistors in the twin-T section. Mylar is the material of choice for the capacitors, and the relative matching of the capacitors and resistors determines the filter's passband symmetry. Using 1% resistors and 5% capacitors produces satisfactory results.

Single-Supply Half-Wave and Full-Wave Rectifiers

An OP291/OP491 configured as a voltage follower operating on a single supply can be used as a simple half-wave rectifier in low-frequency (<2 kHz) applications. A full-wave rectifier can be configured with a pair of OP291s as illustrated in Figure 67. The circuit works in the following way: When the input signal is above 0 V, the output of amplifier A1 follows the input signal. Since the noninverting input of amplifier A2 is connected to A1's output, op amp loop control forces the A2's inverting input to the same potential. The result is that both terminals of R1 are equipotential; i.e., no current flows. Since there is no current flow in R1, the same condition exists upon R2; thus, the output of the circuit tracks the input signal. When the input signal is below 0 V, the output voltage of A1 is forced to 0 V. This condition now forces A2 to operate as an inverting voltage follower because the noninverting terminal of A2 is at 0 V as well. The output voltage at $V_{OUT}A$ is then a full-wave rectified version of the input signal. If needed, a buffered, half-wave rectified version of the input signal is available at $V_{OUT}B$.

Dual/Quad Single Supply Operational Amplifiers

OP292/OP492

FEATURES
Single Supply Operation: 4.5 V to 33 V
Input Common Mode Includes Ground
Output Swings to Ground
High Slew Rate: 3 V/μs
High Gain Bandwidth: 4 MHz
Low Input Offset Voltage
High Open-Loop Gain
No Phase Inversion
Low Cost

APPLICATIONS
Disk Drives
Mobile Phones
Servo Controls
Modems and Fax Machines
Pagers
Power Supply Monitors and Controls
Battery Operated Instrumentation

GENERAL DESCRIPTION

The OP292/OP492 are low cost general purpose dual and quad operational amplifiers designed for single supply applications and are ideal for +5 volt systems.

Fabricated on Analog Devices' CBCMOS process, the OP292/OP492 series has a PNP input stage that allows the input voltage range to include ground. A BiCMOS output stage enables the output to swing to ground while sinking current.

The OP292/OP492 series is unity-gain stable and features an outstanding combination of speed and performance for single or dual supply operation. The OP292/OP492 provide high slew rate, high bandwidth, with open-loop gain exceeding 40,000 and offset voltage under 800 μV (OP292) and 1 mV (OP492). With these combinations of features and low supply current, the OP292/OP492 series is an excellent choice for battery operated applications.

The OP292/OP492 series performance is specified for single or dual supply voltage operation over the extended industrial temperature range (−40°C to +125°C).

Package options for the OP292 and OP492 include plastic DIP, SO-8 (OP292) and SO-14.

APPLICATION INFORMATION

PHASE REVERSAL

The OP492 has built-in protection against phase reversal when the input voltage goes to either supply rail. In fact it is safe for the input to exceed either supply rail by up to 0.6 V with no risk of phase reversal. However, the input should not go beyond the positive supply rail by more than 0.9 V, otherwise the output will reverse phase. If this condition can occur, the problem can be fixed by adding a 5 kΩ current limiting resistor in series with the input pin. With this addition, the input can go to more than 5 V beyond the positive rail without phase reversal.

An input voltage that is as much as 5 V below the negative rail will not result in phase reversal.

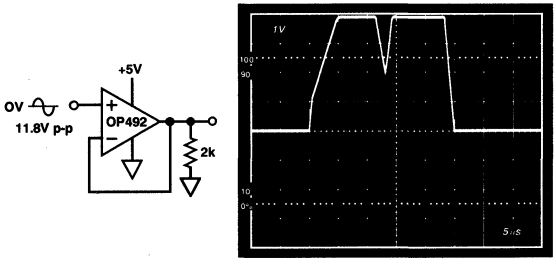

Figure 32. Output Can Reverse Phase If Input Exceeds the Positive Supply (V+) by More Than 0.9 V

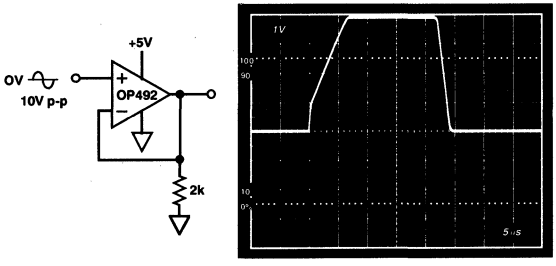

Figure 33. No Negative Rail Phase Reversal, Even with Input Signal at 5 V Below Ground

Power Supply Considerations

The OP292/OP492 are designed to operate equally well at single +5 V or ±15 V supplies. The lowest supply voltage recommended is 4.5 V.

It is a good design practice to bypass the supply pins with a 0.1 μF ceramic capacitor. It helps improve filtering of high frequency noise.

For dual supply operation, the negative supply (V−) must be applied at the same time, or before V+. If V+ is applied before V−, or in the case of a loss of V− supply, while either input is connected to ground or other low impedance source, excessive input current may result. Potentially damaging levels of input current can destroy the amplifier. If this condition can exist, simply add a 1k or larger resistor in series with the input to eliminate the problem.

TYPICAL APPLICATIONS

Direct Access Arrangement for Telephone Line Interface

Figure 34 shows a +5 V-only transmit/receive telephone line interface for a modem circuit. It allows full duplex transmission of modem signals on a transformer-coupled 600 Ω line in a differential manner. The transmit section gain can be set for the specific modem device output. Similarly the receive amplifier gain can be appropriately selected based on the modem device input requirements. The circuit operates on a single +5 V supply. The standard value resistors allow the use of a SIP packaged resistor array; this, coupled with a quad op amp in a single package, offers a compact, low part-count solution.

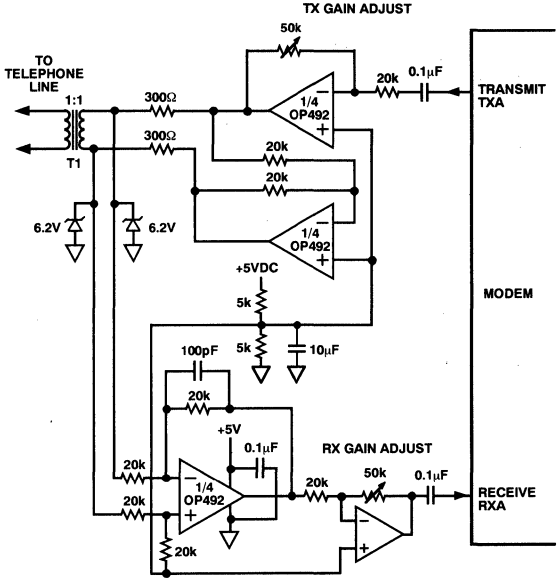

Figure 34. A Universal Direct Access Arrangement for Telephone Line Interface

A Single Supply Instrumentation Amplifier

A low cost single supply instrumentation amplifier can be built as shown in Figure 35. The circuit utilizes two op amps to form a high input impedance differential amplifier. Gain can be set by selecting resistor R_G which can be calculated using the transfer function equation. Normally, $V_{REFERENCE}$ is set to 0 V. Then the output voltage is a function of the gain times the differential input voltage. However, the output can be offset by setting $V_{REFERENCE}$ from 0 V to 4 V, as long as the input common-mode voltage of the amplifier is not exceeded.

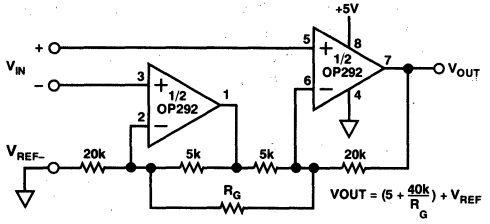

Figure 35. A Single Supply Instrumentation Amplifier

In this configuration, while the output can swing to near zero volts, one needs to be careful because the input's common-mode voltage range cannot operate to zero volts. This is because of the limitation of the circuit configuration where the first amplifier must be able to swing below ground in order to attain a 0 V common-mode voltage, which it cannot do. Depending on the gain of the instrumentation amplifier, the input common-mode extends to within about 0.3 V of zero. One can easily calculate the worst-case common-mode limit for a given gain.

DAC Output Amplifier

The OP292/OP492 are ideal for buffering the output of single supply D/A converters. Figure 36 shows a typical amplifier used to buffer the output of a CMOS DAC that is connected for single supply operation. To do that, the normally current output 12-bit CMOS DAC (R-2R ladder type) is connected backward to produce a voltage output. This operating configuration necessitates a low voltage reference. In this case, a 1.235 V low power reference is used. The relatively high output impedance (10k) is buffered by the OP292 and at the same time gained up to a much more usable level. The potentiometer provides an accurate gain trim for a 4.095 V full-scale, allowing 1 mV increment per LSB of control resolution.

The DAC8043 device comes in an 8-pin DIP package providing a cost-effective, compact solution to a 12-bit analog channel.

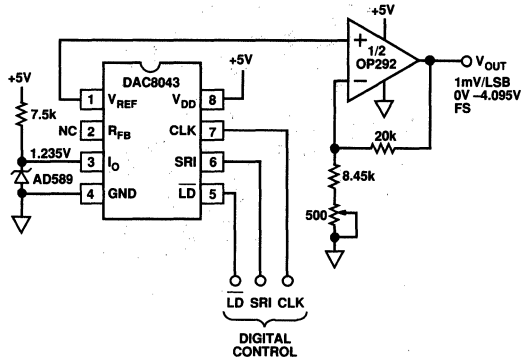

Figure 36. A 12-Bit Single-Supply DAC With Serial Bus Control

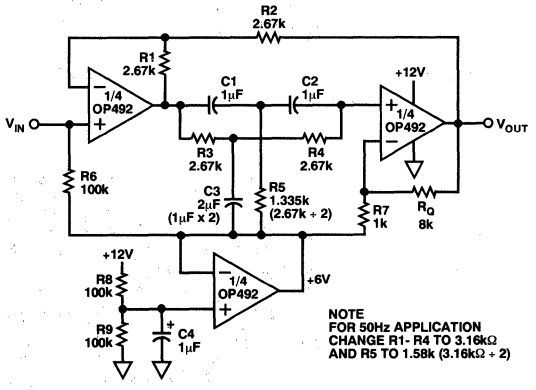
A 50 Hz/60 Hz Single-Supply Notch Filter

Figure 37 shows a notch filter that achieves nearly 30 dB of 60 Hz rejection while powered by only a single 12 V supply. The circuit also works well on +5 V systems. The filter utilizes a twin-T configuration whose frequency selectivity depends heavily on the relative matching of the capacitors and resistors in the twin-T section. Mylar is a good choice for the twin-T's capacitors, and the relative matching of the capacitors and resistors determines the filter's passband symmetry. Using 1% resistors and 5% capacitors produces satisfactory results.

The amount of rejection and the Q of the filter is solely determined by one resistor, and is shown in the table. The bottom amplifier is used to split the supply to bias the amplifier to mid-level. The circuit can be modified to reject 50 Hz by simply changing the resistors in the twin-T section (R1 through R4) from 2.67k to 3.16k, and change R5 to 1/2 of 3.16k. For best results, the common value resistors can be from a resistor array for optimum matching characteristics.



FILTER Q	R_Q (kΩ)	REJECTION (dB)	VOLTAGE GAIN
0.75	1.0	40	1.33
1.00	2.0	35	1.50
1.25	3.0	30	1.60
2.50	8.0	25	1.80
5.00	18	20	1.90
10.00	38	15	1.95

Figure 37. A Single-Supply 50 Hz/60 Hz Notch Filter

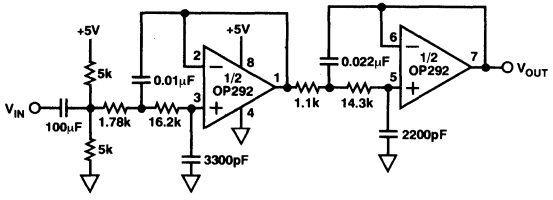


Figure 38. A 4-Pole Bessel Low Pass Filter Using Sallen-Key Topology

A 4-Pole Bessel Low-Pass Filter

The linear phase filter in Figure 38 is designed to roll off at a voiceband cutoff frequency of 3.6 kHz. The 4 poles are formed by two cascading stages of two-pole Sallen-Key filters.

A Low Cost, Linearized Thermistor Amplifier

An inexpensive thermometer amplifier circuit can be implemented using low cost thermistors. One such implementation is shown in Figure 39. The circuit measures temperature over the range of 0°C to +70°C to an accuracy of ±0.3°C as the linearization circuit works well within a narrow temperature range. However, it can measure higher temperature but at a slightly reduced accuracy. To achieve the aforementioned accuracy, the thermistor's nonlinearity must be corrected. This is done by connecting the thermistor in parallel with the 10k in the feedback loop of the first stage amplifier. A constant operating current of 281 µA is supplied by the resistor R1 with the +5 V reference from the REF-195 such that the thermistor's self-heating error is kept below 0.1°C.

In many cases, the thermistor is placed some distance from the signal conditioning circuit. Under this condition, a 0.1 µF capacitor placed across R2 will help to suppress noise pickup.

This linearization network creates an offset voltage which is corrected by summing a compensating current with potentiometer P1. The temperature dependent signal is amplified by the second stage, producing a transfer coefficient of −10 mV/°C at the output.

To calibrate, a precision decade box can be used in place of the thermistor. For 0°C trim, the decade box is set to 32.650k, and P1 is adjusted until the circuit's output reads 0 V. To trim the circuit at the full-scale temperature of 70°C, the decade box is then set to 1.752k and P2 is adjusted until the circuit reads −0.70 V.

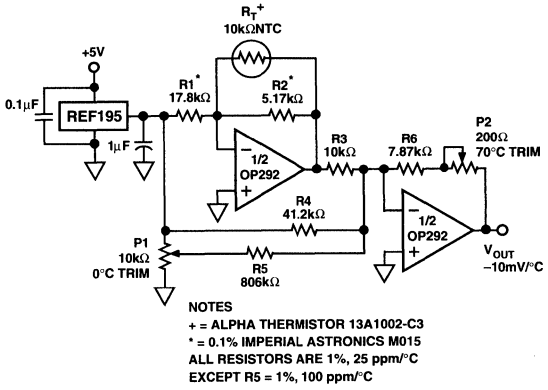

Figure 39. A Low Cost Linearized Thermistor Amplifier

A Single-Supply Ultrasonic Clamping/Limiting Receiver Amplifier

Figure 40 shows an ultrasonic receiver amplifier using the nonlinear impedance of low cost diodes to effectively control the gain for wide dynamic range. This circuit amplifies a 40 kHz ultrasonic signal through a pair of low cost clamping amplifiers before feeding a bandpass filter to extract a clean 40 kHz signal for processing.

The signal is ac-coupled into the false-ground bias node by virtue of the capacitive piezoelectric sensing element. Rather than using an amplifier to generate a supply splitting bias, the false ground voltage is generated by a low cost resistive voltage divider.

Each amplifier stage provides ac gain while passing on the dc self-bias. As long as the output signal at each stage is less than a diode's forward voltage, each amplifier has unrestricted gain to amplify low level signals. However, as the signal strength increases, the feedback diodes begin to conduct, shunting the feedback current, and thus reducing the gain. Although distorting the waveform, the diodes effectively maintain a relatively constant amplitude even with large signals that otherwise would saturate the amplifier. In addition, this design is considerably more stable than the feedback type AGC.

The overall circuit has a gain range from −2 to −400, where the inversion comes from the bandpass filter stage. Operating with a Q of 5, the filter restores a clean, undistorted signal to the output. The circuit also work well with 5 V supply systems.

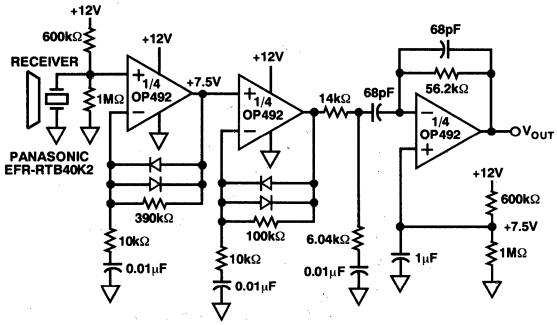

Figure 40. A 40 kHz Ultrasonic Clamping/Limiting Receiver Amplifier

Precision Single-Supply Voltage Comparator

The OP292/OP492 have excellent overload recovery characteristics, making them suitable for precision comparator applications. Figure 41 shows the saturation recovery characteristics of the OP492. The amplifier exhibits very little propagation delay. The amplifier compares a signal precisely to less than 0.5 mV offset error.

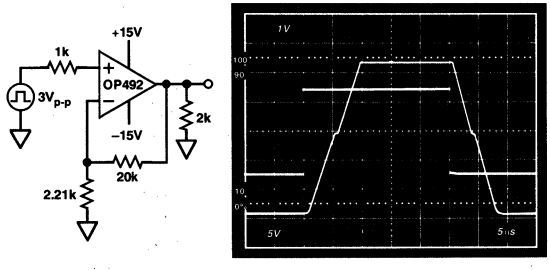

Figure 41. The OP492 Has Fast Overload Recovery for Comparator Applications

Programmable Precision Window Comparator

The OP292/OP492 can be used for precise level detection such as in test equipment where a signal is measured within a range. Figure 42 shows such an implementation. The threshold voltage level is set by a pair of 12-bit D/A converters. The DACs have serial interface thus minimizing interconnection requirements. The DAC8512 has a control resolution of 1 mV/bit. Thus for 5 V supply operation, maximum DAC output is 4.095 V. However, the OP292 will accept a maximum input of 4.0 V.

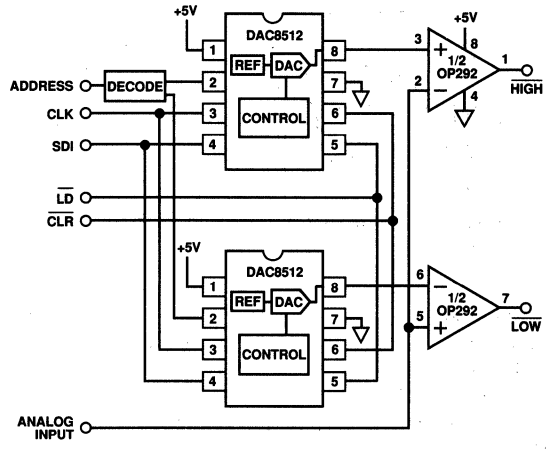

Figure 42. Programmable Window Comparator with 12-Bit Threshold Level Control

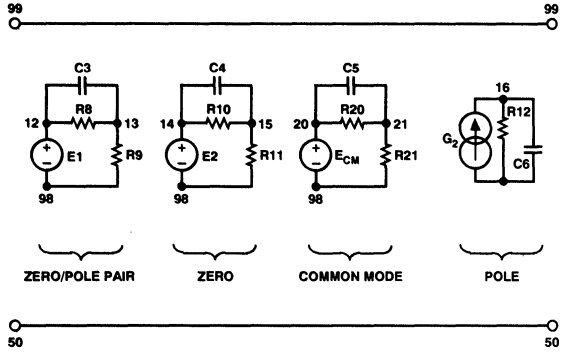
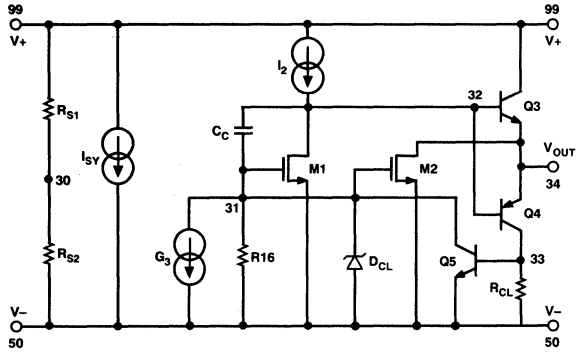
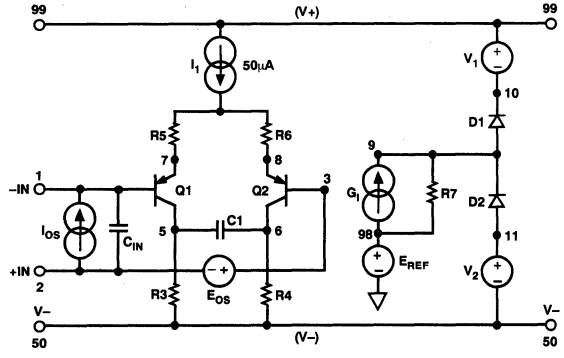
OP292/OP492 SPICE







Dual/Quad Rail-to-Rail Operational Amplifiers

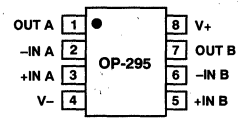
OP295/OP495

FEATURES
Rail-to-Rail Output Swing
Single-Supply Operation: +3 V to 36 V
Low Offset Voltage: 300 μV
Gain Bandwidth Product: 75 kHz
High Open-Loop Gain: 1000 V/mV
Unity-Gain Stable
Low Supply Current/Per Amplifier: 150 μA max

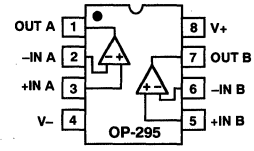
APPLICATIONS
Battery Operated Instrumentation
Servo Amplifiers
Actuator Drives
Sensor Conditioners
Power Supply Control

PIN CONNECTIONS

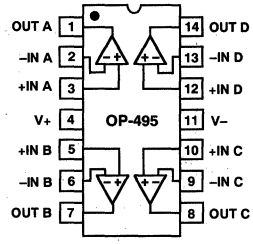
8-Lead Narrow-Body SO
(S Suffix)



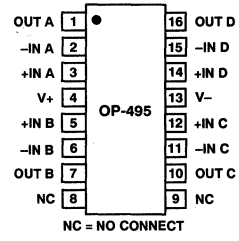
8-Lead Epoxy DIP
(P Suffix)



14-Lead Epoxy DIP
(P Suffix)



16-Lead SOL (300 Mil)
(S Suffix)



GENERAL DESCRIPTION

Rail-to-rail output swing combined with dc accuracy are the key features of the OP-495 quad and OP-295 dual CBCMOS operational amplifiers. By using a bipolar front end, lower noise and higher accuracy than CMOS designs have been achieved. Both input and output ranges include the negative supply providing the user "zero-in/zero-out" capability. For users of 3.3 volt systems such as lithium batteries, the OP-295/OP-495 is specified for three volt operation.

Maximum offset voltage is specified at 300 μV for +5 volt operation, and the open-loop gain is a minimum of 1000 V/mV, giving the user performance that can be used to implement high accuracy systems even in single supply designs.

The ability to swing rail-to-rail and supply ±15 mA to the load makes the OP-295/OP-495 an ideal driver for power transistors and "H" bridges. This allows designs to achieve higher efficiencies and to transfer more power to the load than previously possible without the use of discrete components. For applications that require driving inductive loads, such as transformers, increases in efficiency are also possible. Stability while driving capacitive loads is another benefit of this design over CMOS rail-to-rail amplifiers. This is useful for driving coax cable or large FET transistors. The OP-295/OP-495 is stable with loads in excess of 300 pF.

The OP-295 and OP-495 are specified over the extended industrial (−40°C to +125°C) temperature range. OP-295s are available in 8-pin plastic and ceramic DIP plus SO-8 surface mount packages. OP-495s are available in 14-pin plastic and SOL-16 surface mount packages. Contact your local sales office for MIL-STD-883 data sheet.

Output Voltage Swing High	V_{OH}	R_L = 10 kΩ	4.9	V min
Supply Current Per Amplifier	I_{SY}	V_{OUT} = 2.5 V, R_L = ∞	150	μA max

NOTES
Electrical tests and wafer probe to the limits shown. Due to variations in assembly methods and normal yield loss, yield after packaging is not guaranteed for standard product dice. Consult factory to negotiate specifications based on dice lot qualifications through sample lot assembly and testing.
[1]Guaranteed by CMR test.

P, S Package . . . . . −65°C to +150°C
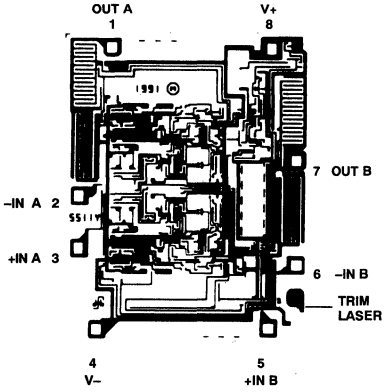
Lead Temperature Range (Soldering, 60 Sec) . . . . . +300°C

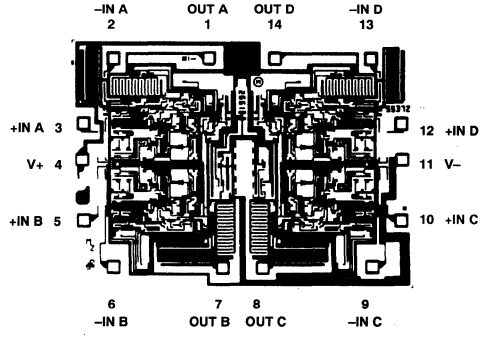
Package Type	θ_{JA}[3]	θ_{JC}	Units
8-Pin Plastic DIP (P)	103	43	°C/W
8-Pin SOIC (S)	158	43	°C/W
14-Pin Plastic DIP (P)	83	39	°C/W
16-Pin SOL (S)	98	30	°C/W

NOTES
[1]Absolute maximum ratings apply to both DICE and packaged parts, unless otherwise noted.
[2]For supply voltages less than ±18 V, the absolute maximum input voltage is equal to the supply voltage.
[3]θ_{JA} is specified for the worst case conditions, i.e., θ_{JA} is specified for device in socket for cerdip, P-DIP, and LCC packages; θ_{JA} is specified for device soldered in circuit board for SOIC package.

DICE CHARACTERISTICS



OP-295 Die Size 0.066 × 0.080 inch, 5,280 sq. mils.
Substrate (Die Backside) Is Connected to V+.
Transistor Count, 74.



OP-495 Die Size 0.113 × 0.083 inch, 9,380 sq. mils.
Substrate (Die Backside) Is Connected to V+.
Transistor Count, 196.

APPLICATIONS

Rail-to-Rail Applications Information

The OP-295/OP-495 has a wide common-mode input range extending from ground to within about 800 mV of the positive supply. There is a tendency to use the OP-295/OP-495 in buffer applications where the input voltage could exceed the common-mode input range. This may initially appear to work because of the high input range and rail-to-rail output range. But above the common-mode input range the amplifier is, of course, highly nonlinear. For this reason it is always required that there be some minimal amount of gain when rail-to-rail output swing is desired. Based on the input common-mode range this gain should be at least 1.2.

Low Drop-Out Reference

The OP-295/OP-495 can be used to gain up a 2.5 V or other low voltage reference to 4.5 volts for use with high resolution A/D converters that operate from +5 volt only supplies. The circuit in Figure 1 will supply up to 10 mA. Its no-load drop-out voltage is only 20 mV. This circuit will supply over 3.5 mA with a +5 volt supply.

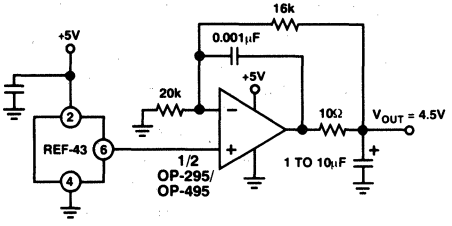

Figure 1. 4.5 Volt, Low Drop-Out Reference

Low Noise, Single Supply Preamplifier

Most single supply op amps are designed to draw low supply current, at the expense of having higher voltage noise. This tradeoff may be necessary because the system must be powered by a battery. However, this condition is worsened because all circuit resistances tend to be higher, as a result, in addition to the op amp's voltage noise, Johnson noise (resistor thermal noise) is also a significant contributor to the total noise of the system.

The choice of monolithic op amps that combine the characteristics of low noise and single supply operation is rather limited. Most single supply op amps have noise on the order of 30 to 60 nV/$\sqrt{\text{Hz}}$ and single supply amplifiers with noise below 5 nV/$\sqrt{\text{Hz}}$ do not exist.

In order to achieve both low noise and low supply voltage operation, discrete designs may provide the best solution. The circuit on Figure 2 uses the OP-295/OP-495 rail-to-rail amplifier and a matched PNP transistor pair – the MAT03 – to achieve zero-in/zero-out single supply operation with an input voltage noise of 3.1 nV/$\sqrt{\text{Hz}}$ at 100 Hz. R5 and R6 set the gain of 1000, making this circuit ideal for maximizing dynamic range when amplifying low level signals in single supply applications. The OP-295/OP-495 provides rail-to-rail output swings allowing this circuit to operate with 0 to 5 volt outputs. Only half of the OP-295/OP-495 is used leaving the other uncommitted op amp for use elsewhere.

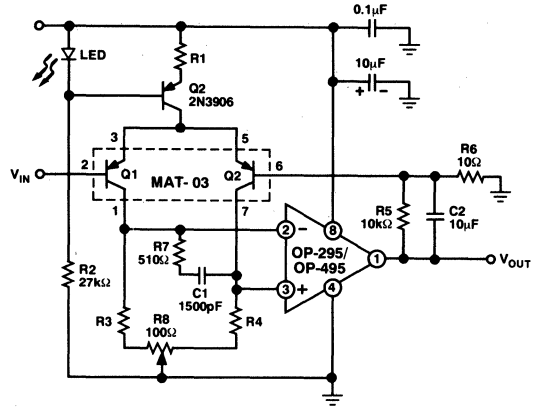

Figure 2. Low Noise Single Supply Preamplifier

The input noise is controlled by the MAT-03 transistor pair and its collector current level. Increasing the collector current reduces the voltage noise. This particular circuit was tested with 1.85 mA and 0.5 mA of current. Under these two cases, the input voltage noise was 3.1 nV/$\sqrt{\text{Hz}}$ and 10 nV/$\sqrt{\text{Hz}}$, respectively. The high collector currents do lead to a tradeoff in supply current, bias current, and current noise. All of these parameters will increase with increasing collector current. For example, typically the MAT-03 has an h_{FE} = 165. This leads to bias currents of 11 µA and 3 µA, respectively. Based on high bias currents, this circuit is best suited for applications with low source impedance such as magnetic pickups or low impedance strain gauges. Furthermore, a high source impedance will degrade the noise performance. For example, a 1 kΩ resistor generates 4 nV/$\sqrt{\text{Hz}}$ of broad band noise, which is already greater than the preamp.

The collector current is set by R1 in combination with the LED and Q2. The LED is a 1.6 V "Zener" that has temperature coefficient close to that of Q2's base-emitter junction, which provides a constant 1.0 V drop across R1. With R1 equal to 270 Ω, the tail current is 3.7 mA, and the collector current is half that or 1.85 mA. The value of R1 can be altered to adjust the collector current. Whenever R1 is changed, R3 and R4 should also be adjusted. To maintain a common-mode input range that includes ground, the collectors of the Q1 and Q2 should not go above 0.5 V, otherwise they could saturate. Thus, R3 and R4 have to be small enough to prevent this condition. Their values and the overall performance for two different values of R1 are summarized in Table I. Lastly, the potentiometer, R8, is needed to adjust the offset voltage to null it to zero. Similar performance can be obtained using an OP-90 as the output amplifier with a savings of about 185 µA of supply current. However, the output swing will not include the positive rail, and the bandwidth will reduce to approximately 250 Hz.

Table I. Single Supply Low Noise Preamp Performance

	I_C = 1.85 mA	I_C = 0.5 mA
R1	270 Ω	1.0 kΩ
R3, R4	200 Ω	910 Ω
e_n @ 100 Hz	3.15 nV/√Hz	8.6 nV/√Hz
e_n @ 10 Hz	4.2 nV/√Hz	10.2 nV/√Hz
I_{SY}	4.0 mA	1.3 mA
I_B	11 μA	3 μA
Bandwidth	1 kHz	1 kHz
Closed-Loop Gain	1000	1000

Driving Heavy Loads

The OP-295/OP-495 is well suited to drive loads by using a power transistor, Darlington or FET to increase the current to the load. The ability to swing to either rail can assure that the device is turned on hard. This results in more power to the load and an increase in efficiency over using standard op amps with their limited output swing. Driving power FETs is also possible with the OP-295/OP-495 because of its ability to drive capacitive loads of several hundred picofarads without oscillating.

Without the addition of external transistors the OP-295/OP-495 can drive loads in excess of ±15 mA with ±15 or 30 volt supplies. This drive capability is somewhat decreased at lower supply voltages. At ±5 volt supplies the drive current is ±11 mA.

Driving motors or actuators in two directions, in a single supply application is often accomplished using an "H" bridge. The principle is demonstrated in Figure 3a. From a single +5 volt supply this driver is capable of driving loads from 0.8 to 4.2 volts in both directions. Figure 3b shows the voltages at the inverting and noninverting outputs of the driver. There is a small crossover glitch that is frequency dependent and would not cause problems unless this was a low distortion application such as audio. If this is used to drive inductive loads, be sure to add diode clamps to protect the bridge from inductive kickback.

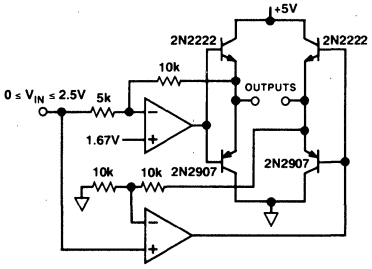

Figure 3a. "H" Bridge

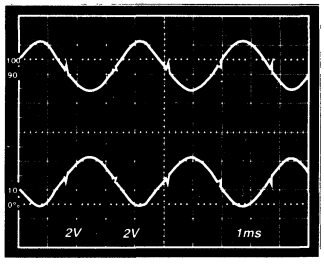

Figure 3b. "H" Bridge Outputs

Direct Access Arrangement

OP-295/OP-495 can be used in a single supply Direct Access Arrangement (DAA) as is shown in Figure 4. This figure shows a portion of a typical DAA capable of operating from a single +5 volt supply and it may also work on +3 volt supplies with minor modifications. Amplifiers A2 and A3 are configured so that the transmit signal TXA is inverted by A2 and is not inverted by A3. This arrangement drives the transformer differentially so that the drive to the transformer is effectively doubled over a single amplifier arrangement. This application takes advantage of the OP-295/OP-495's ability to drive capacitive loads, and to save power in single supply applications.

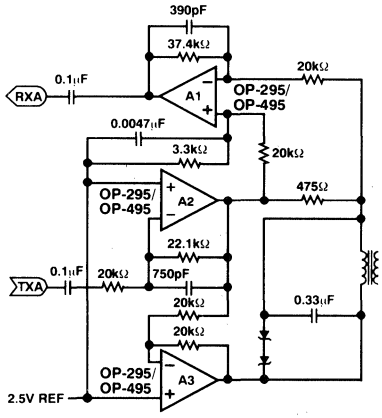

Figure 4. Direct Access Arrangement

A Single Supply Instrumentation Amplifier

The OP-295/OP-495 can be configured as a single supply instrumentation amplifier as in Figure 5. The input common-mode voltage range includes ground and the output swings to both rails.

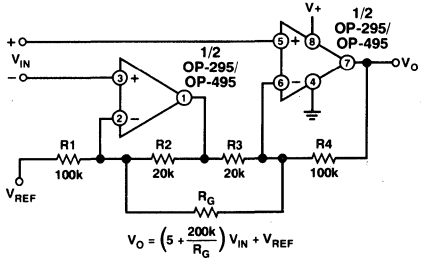

Figure 5. Single Supply Instrumentation Amplifier

Resistor R_G sets the gain of the instrumentation amplifier. Minimum gain is 6 (with no R_G). All resistors should be matched in absolute value as well as temperature coefficient to maximize common-mode rejection performance and minimize drift. This instrumentation amplifier can operate from a supply voltage as low as 3 volts.

A Single Supply RTD Thermometer Amplifier

This RTD amplifier takes advantage of the rail-to-rail swing of the OP-295/OP-495 to achieve a high bridge voltage in spite of a low 5 V supply. The OP-295/OP-495 amplifier servos a constant 200 μA current to the bridge. The return current drops across the parallel resistors 6.19 kΩ and the 2.55 MΩ, developing a voltage that is servoed to 1.235 V, which is established by the AD589 bandgap reference. The 3-wire RTD provides a equal line resistance drop in both 100 Ω legs of the bridge, thus improving the accuracy.

The AMP-04 amplifies the differential bridge signal and converts it to a single-ended output. The gain is set by the series resistance of the 332 Ω resistor plus the 50 Ω potentiometer. The gain scales the output to produce a 4.5 V full scale. The 0.22 μF capacitor to the output provides a 7 Hz low-pass filter to keep noise at a minimum.

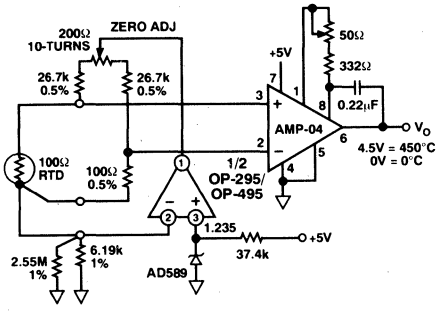

Figure 6. Low Power RTD Amplifier

A Cold Junction Compensated, Battery Powered Thermocouple Amplifier

The OP-295/OP-495's 150 μA quiescent current per amplifier consumption makes it useful for battery powered temperature measuring instruments. The K-type thermocouple terminates into an isothermal block where the terminated junctions' ambient temperature can be continuously monitored and corrected by summing an equal but opposite thermal EMF to the amplifier, thereby canceling the error introduced by the cold junctions.

To calibrate, immerse the thermocouple measuring junction in a 0°C ice bath, adjust the 500 Ω Zero Adjust pot to zero volts out. Then immerse the thermocouple in a 250°C temperature bath or oven and adjust the Scale Adjust pot for an output voltage of 2.50 V, which is equivalent to 250°C. Within this temperature range, the K-type thermocouple is quite accurate and produces a fairly linear transfer characteristic. Accuracy of ±3°C is achievable without linearization.

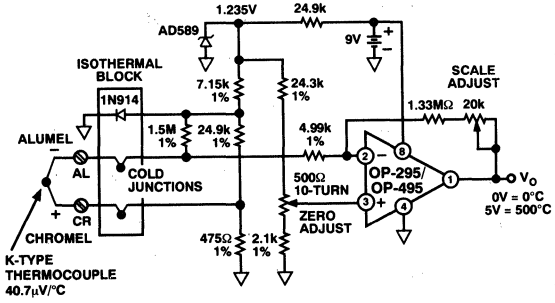

Figure 7. Battery Powered, Cold-Junction Compensated Thermocouple Amplifier

Even if the battery voltage is allowed to decay to as low as 7 volts, the rail-to-rail swing allows temperature measurements to 700°C. However, linearization may be necessary for temperatures above 250°C where the thermocouple becomes rather nonlinear. The circuit draws just under 500 μA supply current from a 9 V battery.

A 5 V Only, 12-Bit DAC That Swings 0 V to 4.095 V

Figure 8 shows a complete voltage output DAC with wide output voltage swing operating off a single +5 V supply. The serial input 12-bit D/A converter is configured as a voltage output device with the 1.235 V reference feeding the current output pin (I_{OUT}) of the DAC. The V_{REF} which is normally the input, now becomes the output.

The output voltage from the DAC is the binary weighted voltage of the reference, which is gained up by the output amplifier such that the DAC has a 1 mV per bit transfer function.

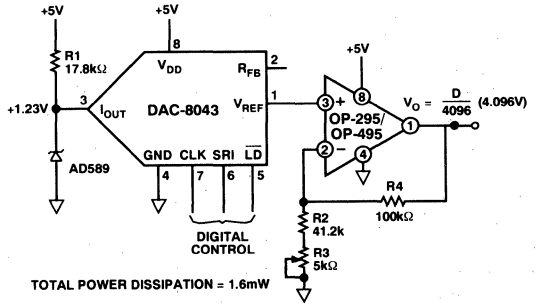

Figure 8. A 5 Volt 12-Bit DAC with 0 V to +4.095 Output Swing

4–20mA Current Loop Transmitter

Figure 9 shows a self-powered 4–20 mA current loop transmitter. The entire circuit floats up from the single supply (12 V to 36 V) return. The supply current carries the signal within the 4 mA to 20 mA range. Thus the 4 mA establishes the baseline

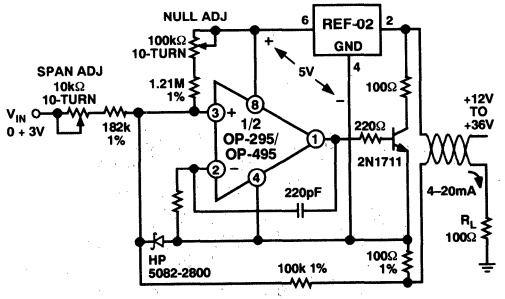

Figure 9. 4–20 mA Current Loop Transmitter

current budget with which the circuit must operate. This circuit consumes only 1.4 mA maximum quiescent current, making 2.6 mA of current available to power additional signal conditioning circuitry or to power a bridge circuit.

A 3 Volt Low-Dropout Linear Voltage Regulator

Figure 10 shows a simple 3 V voltage regulator design. The regulator can deliver 50 mA load current while allowing a 0.2 V dropout voltage. The OP-295/OP-495's rail-to-rail output swing handily drives the MJE350 pass transistor without requiring special drive circuitry. At no load, its output can swing less than the pass transistor's base-emitter voltage, turning the device nearly off. At full load, and at low emitter-collector voltages, the transistor beta tends to decrease. The additional base current is easily handled by the OP-295/OP-495 output.

The amplifier servos the output to a constant voltage, which feeds a portion of the signal to the error amplifier.

Higher output current, to 100 mA, is achievable at a higher dropout voltage of 3.8 V.

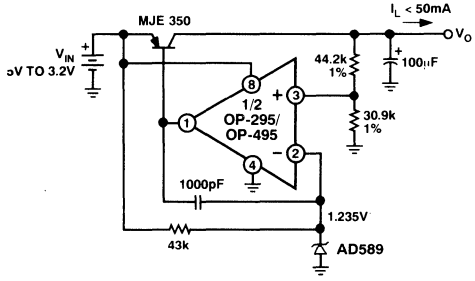

Figure 10. 3 V Low Dropout Voltage Regulator

Figure 11 shows the regulator's recovery characteristic when its output underwent a 20 mA to 50 mA step current change.

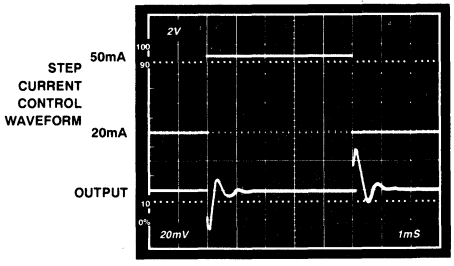

Figure 11. Output Step Load Current Recovery

Low Dropout, 500 mA Voltage Regulator with Fold-Back Current Limiting

Adding a second amplifier in the regulation loop as shown in Figure 12 provides an output current monitor as well as provides fold-back current limiting protection.

Amplifier A1 provides error amplification for the normal voltage regulation loop. As long as the output current is less than 1 ampere, amplifier A2's output swings to ground, reverse biasing the diode and effectively taking itself out of the circuit. However, as the output current exceeds 1 amp, the voltage that develops across the 0.1 Ω sense resistor forces the amplifier A2's output to go high, forward-biasing the diode, which in turn closes the current limit loop. At this point A2's lower output resistance dominates the drive to the power MOSFET transistor, thereby effectively removing the A1 voltage regulation loop from the circuit.

If the output current greater than 1 amp persists, the current limit loop forces a reduction of current to the load, which causes a corresponding drop in output voltage. As the output voltage drops, the current limit threshold also drops fractionally, resulting in a decreasing output current as the output voltage decreases, to the limit of less than 0.2 A at 1 V output. This "fold-back" effect reduces the power dissipation considerably during a short circuit condition, thus making the power supply far more forgiving in terms of the thermal design requirements. Small heat sinking on the power MOSFET can be tolerated.

The OP-295's rail-to-rail swing exacts higher gate drive to the power MOSFET, providing a fuller enhancement to the transistor. The regulator exhibits 0.2 V drop-out at 500 mA of load current. At 1 amp output, the drop-out voltage is typically 5.6 volts.

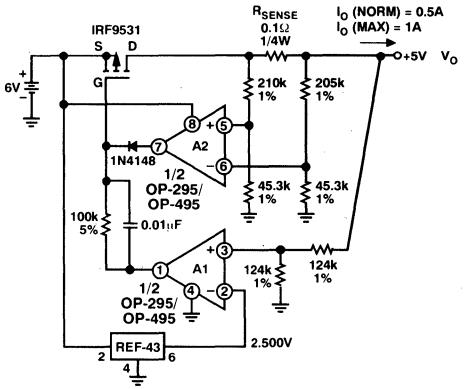

Figure 12. Low Dropout, 500 mA Voltage Regulator with Fold-back Current Limiting

Square Wave Oscillator

The oscillator circuit in Figure 13 shows the rail-to-rail swing helps maintain a constant oscillation frequency even though the supply voltage varies considerably. This works great in a battery powered system where no voltage regulation is required. The constant frequency comes from the fact that the 58.7 kΩ feedback sets up Schmitt Trigger threshold levels that are directly proportional to the supply voltage, as are the RC charge voltage levels. As a result, the RC charge time, and therefore the frequency, remain constant independent of supply voltage. The slew rate of the amplifier limits the oscillation frequency to a maximum of about 800 Hz at +5 V supply.

Single Supply Differential Speaker Driver

Connected as a differential speaker driver, the OP-295/OP-495 can deliver a minimum of 10 mA to the load. With a 600 Ω load, the OP-295/OP-495 can swing close to 5 volts peak-to-peak across the load.

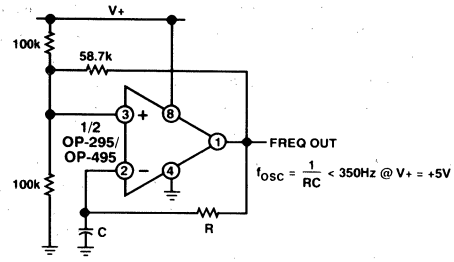

Figure 13. Square Wave Oscillator Has Stable Frequency Regardless of Supply Changes

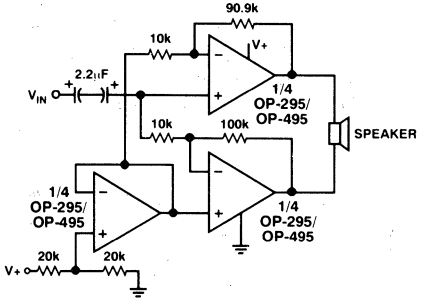

Figure 14. Single Supply Differential Speaker Driver

High Accuracy, Single Supply, Low Power Comparator
The OP-295/OP-495 makes an accurate open-loop comparator. With single +5 V supply, the offset error is less than 300 μV. Figure 15 shows the OP-295/OP495's response time operating open-loop with 4 mV overdrive. It exhibits a 4 ms response time at the rising edge and a 1.5 ms response time at the falling edge.

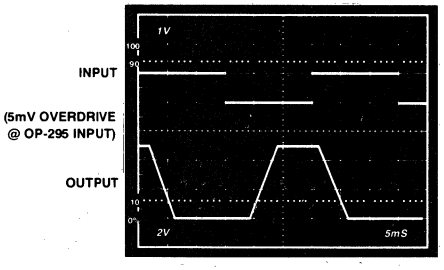

Figure 15. Open-Loop Comparator Response Time with 5 mV Overdrive

Dual Low Bias Current Precision Operational Amplifier

OP297

FEATURES

- **Precision Performance in Standard SO-8 Pinout**
- **Low Offset Voltage ..... 50μV Max**
- **Low Offset Voltage Drift ..... 0.6μV/°C Max**
- **Very Low Bias Current**
  +25°C ..... 100pA Max
  –55°C to +125°C ..... 450pA Max
- **Very High Open-Loop Gain ..... 2000V/mV Min**
- **Low Supply Current (Per Amplifier) ..... 625μA Max**
- **Operates From ±2V to ±20V Supplies**
- **High Common-Mode Rejection ..... 120dB Min**
- **Pin Compatible to LT1013, AD706, AD708, OP-221, LM158, and MC1458/1558 with Improved Performance**

APPLICATIONS

- **Strain Guage and Bridge Amplifiers**
- **High Stability Thermocouple Amplifiers**
- **Instrumentation Amplifiers**
- **Photo-Current Monitors**
- **High-Gain Linearity Amplifiers**
- **Long-Term Integrators/Filters**
- **Sample-and-Hold Amplifiers**
- **Peak Detectors**
- **Logarithmic Amplifiers**
- **Battery-Powered Systems**

GENERAL DESCRIPTION

The OP-297 is the first dual op amp to pack precision performance into the space-saving, industry standard 8-pin SO package. Its combination of precision with low power and extremely low input bias current makes the dual OP-297 useful in a wide variety of applications.

Precision performance of the OP-297 includes very low offset, under 50μV, and low drift, below 0.6μV/°C. Open-loop gain exceeds 2000V/mV insuring high linearity in every application. Errors due to common-mode signals are eliminated by the OP-297's common-mode rejection of over 120dB. The OP-297's power supply rejection of over 120dB minimizes offset voltage changes experienced in battery powered systems. Supply current of the OP-297 is under 625μA per amplifier and it can operate with supply voltages as low as ±2V. *Continued*

GENERAL DESCRIPTION *Continued*

The OP-297 utilizes a super-beta input stage with bias current cancellation to maintain picoamp bias currents at all temperatures. This is in contrast to FET input op amps whose bias currents start in the picoamp range at 25°C, but double for every 10°C rise in temperature, to reach the nanoamp range above 85°C. Input bias current of the OP-297 is under 100pA at 25°C and is under 450pA over the military temperature range.

Combining precision, low power and low bias current, the OP-297 is ideal for a number of applications including instrumentation amplifiers, log amplifiers, photo-diode preamplifiers and long-term integrators. For a single device, see the OP-97; for a quad, see the OP-497.

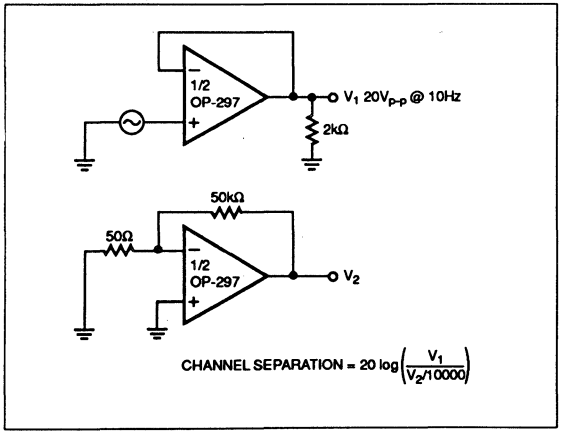
CHANNEL SEPARATION TEST CIRCUIT



Quad Low-Offset, Low-Power Operational Amplifier

OP400

FEATURES

- Low Input Offset Voltage ..... 150μV Max
- Low Offset Voltage Drift, Over –55°C to +125°C ..... 1.2μV/°C Max
- Low Supply Current (Per Amplifier) ..... 725μA Max
- High Open-Loop Gain ..... 5000V/mV Min
- Input Bias Current ..... 3nA Max
- Low Noise Voltage Density ..... 11nV/$\sqrt{Hz}$ at 1kHz
- Stable With Large Capacitive Loads ..... 10nF Typ
- Pin Compatible to OP-11, LM148, HA4741, RM4156, and LT1014 With Improved Performance
- Available in Die Form

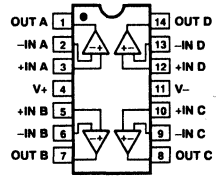
GENERAL DESCRIPTION

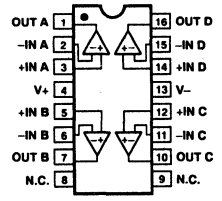
The OP-400 is the first monolithic quad operational amplifier that features OP-77 type performance. Precision performance no longer has to be sacrificed to obtain the space and cost savings offered by quad amplifiers.

The OP-400 features an extremely low input offset voltage of less than 150μV with a drift of under 1.2μV/°C, guaranteed

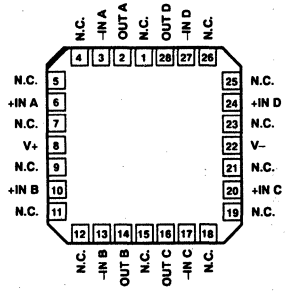
PIN CONNECTIONS



14-PIN HERMETIC DIP (Y-Suffix)
14-PIN PLASTIC DIP (P-Suffix)

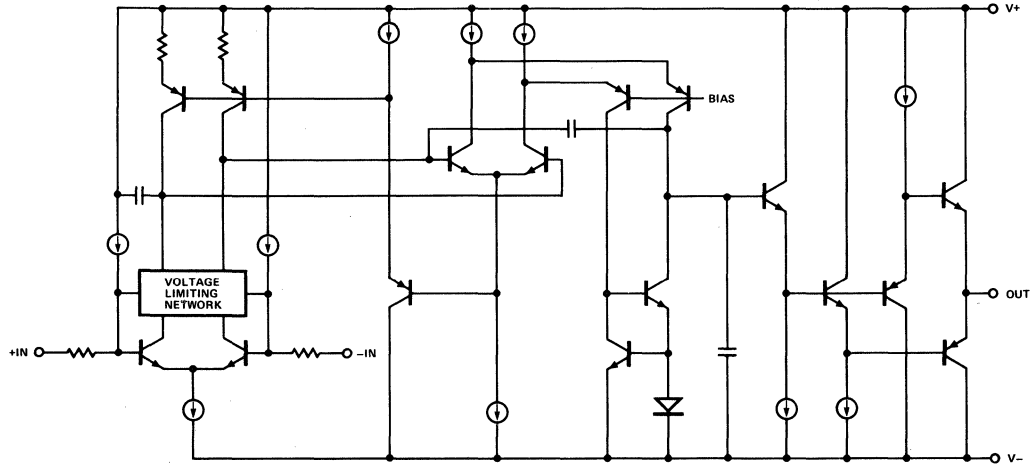


16-PIN SOL (S-Suffix)



28-LEAD LCC (TC-Suffix)

SIMPLIFIED SCHEMATIC (One of four amplifiers is shown.)



This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

over the full military temperature range. Open-loop gain of the OP-400 is over 5,000,000 into a 10kΩ load; input bias current is under 3nA; CMR is above 120dB and PSRR below 1.8μV/V. On-chip zener-zap trimming is used to achieve the low input offset voltage of the OP-400 and eliminates the need for offset nulling. (The OP-400 conforms to the industry-standard quad pinout which does not have null terminals.)

The OP-400 features low power consumption, drawing less than 725μA per amplifier. The total current drawn by this quad amplifier is less than that of a single OP-07, yet the OP-400 offers significant improvements over this industry-standard op amp. Voltage noise density of the OP-400 is a low $11nV/\sqrt{Hz}$ at 10Hz which is half that of most competitive devices.

The OP-400 is pin compatible with the OP-11, LM148, HA4741, RM4156, and LT1014 operational amplifiers and can be used to upgrade systems using these devices. The OP-400 is an ideal choice for applications requiring multiple precision operational amplifiers and where low power consumption is critical.

GENERAL DESCRIPTION

The OP-420 quad micropower operational amplifier is a single-chip quad patterned after the OP-20 precision micropower single operational amplifier. A Darlington PNP input stage allows the input common-mode voltage to include V−. The wide input range combined with low power-supply drain (~40μA/section at 5V), provides a unique solution for designs requiring high functional density and portable operation. Applications include two-wire transmitters for process control loops, battery-operated remote-line filters, signal preconditioning amplifiers, and a variety of multiple-gain block arrays.

For micropower applications requiring offset nulling, see the OP-20, OP-21 and OP-22 data sheets.

Quad Precision, High Speed Operational Amplifier

OP467

FEATURES
High Slew Rate – 170 V/μs
Wide Bandwidth – 28 MHz
Fast Settling Time – <200 ns to 0.01%
Low Offset Voltage – <500 μV
Unity-Gain Stable
Low Voltage Operation ±5 V to ±15 V
Low Supply Current – <10 mA
Drives Capacitive Loads

APPLICATIONS
High Speed Image Display Drivers
High Frequency Active Filters
Fast Instrumentation Amplifiers
High Speed Detectors
Integrators
Photo Diode Preamps

GENERAL DESCRIPTION

The OP-467 is a quad, high speed, precision operational amplifier. It offers the performance of a high speed op amp combined with the advantages of a precision operational amplifier all in a single package. The OP-467 is an ideal choice for applications where, traditionally, more than one op amp was used to achieve this level of speed and precision.

The OP-467's internal compensation ensures stable unity-gain operation, and it can drive large capacitive loads without oscillation. With a gain bandwidth product of 28 MHz driving a 30 pF load, output slew rate in excess of 170 V/μs, and settling time to 0.01% in less than 200 ns, the OP-467 provides excellent dynamic accuracy in high speed data-acquisition systems. The channel-to-channel separation is typically 60 dB at 10 MHz.

The dc performance of OP-467 includes less than 0.5 mV of offset, voltage noise density below 6 nV/$\sqrt{\text{Hz}}$ and total supply current under 10 mA. Common-mode rejection and power supply rejection ratios are typically 85 dB. PSRR is maintained to better than 40 dB with input frequencies as high as 1 MHz. The low offset and drift plus high speed and low noise, make the OP-467 usable in applications such as high speed detectors and instrumentation.

The OP-467 is specified for operation from ±5 V to ±15 V over the extended industrial temperature range (−40°C to +85°C) and is available in 14-pin plastic and ceramic DIP, plus SOL-16 and 20-lead LCC surface mount packages.

APPLICATIONS INFORMATION

OUTPUT SHORT-CIRCUIT PERFORMANCE

To achieve a wide bandwidth and high slew rate, the OP-467 output is *not* short circuit protected. Shorting the output to ground or to the supplies may destroy the device.

For safe operation, the output load current should be limited so that the junction temperature does not exceed the absolute maximum junction temperature.

To calculate the maximum internal power dissipation, following formula can be used:

$$PD = \frac{T_J\ max - T_A}{\theta_{JA}}$$

where T_J and T_A are junction and ambient temperatures respectively, PD is device internal power dissipation, and θ_{JA} is packaged device thermal resistance given in the data sheet.

UNUSED AMPLIFIERS

It is recommended that any unused amplifiers in a quad package be connected as a unity gain follower with a 1 kΩ feedback resistor with noninverting input tied to the ground plain.

PRINTED CIRCUIT BOARD LAYOUT CONSIDERATIONS

Satisfactory performance of a high speed op amp largely depends on a good PC layout. To achieve the best dynamic performance, following high frequency layout technique is recommended.

GROUNDING

A good ground plain is essential to achieve the optimum performance in high speed applications. It can significantly reduce the undesirable effects of ground loops and IR drops by providing a low impedance reference point. Best results are obtained with a multilayer board design with one layer assigned to ground plain. To maintain a continuous and low impedance ground, avoid running any traces on this layer.

POWER SUPPLY CONSIDERATIONS

In high frequency circuits, device lead length introduces an inductance in series with the circuit. This inductance combined with stray capacitance forms a high frequency resonance circuit. Poles generated by these circuits will cause gain peaking and additional phase shift reducing the op amp's phase margin and leading to an unstable operation.

A practical solution to this problem is to reduce the resonance frequency low enough to take advantage of the amplifier's power supply rejection.

This is easily done by placing capacitors across the supply line and the ground plain as close as possible to the device pin. Since capacitors also have internal parasitic components, such as stray inductance, selecting the right capacitor is important. To be effective, they should have low impedance over the frequency range of interest. Tantalum capacitors are an excellent choice for their high capacitance/size ratio, but their ESR (Effective Series Resistance) increases with frequency making them less effective. On the other hand, ceramic chip capacitors have excellent ESR and ESL (Effective Series Inductance) performance at higher frequencies, and because of their small size, they can be placed very close to the device pin, further reducing the stray inductance. Best results are achieved by using a combination of these two capacitors. A 5–10 μF tantalum parallel with a 0.1 μF ceramic chip caps are recommended. If additional isolation from high frequency resonances of the power supply is needed, a ferrite bead should be placed in series with the supply lines between the bypass caps and the power supply. A word of caution, addition of the ferrite bead will introduce a new pole and zero to frequency response of the circuit and could cause unstable operation if it is not selected properly.

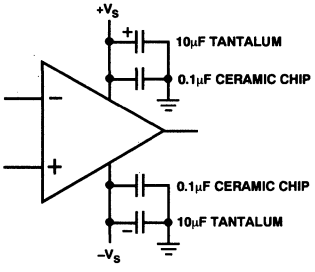

Figure 35. Recommended Power Supply Bypass

SIGNAL CONSIDERATIONS

Input and output traces need special attention to assure a minimum stray capacitance. Input nodes are very sensitive to capacitive reactance, particularly when connected to a high impedance circuit. Stray capacitance can inject undesirable signals from a noisy line into a high impedance input. Protect high impedance input traces by providing guard traces around them. This will also improve the channel separation significantly.

Additionally, any stray capacitance in parallel with the op amp's input capacitance generates a pole in the frequency response of the circuit. The additional phase shift caused by this pole will reduce the circuit's gain margin. If this pole is within the gain range of the op amp, it will cause unstable performance. To reduce these undesirable effects, use the lowest impedance where possible. Lowering the impedance at this node places the poles at a higher frequency, far above the gain range of the amplifier. Stray capacitance on the PC board can be reduced by making the traces narrow and as short as possible. Further reduction can be realized by choosing smaller pad size, increasing the spacing between the traces, and using PC board material with a low dielectric constant insulator (Dielectric Constant of some common insulators: air = 1, Teflon = 2.2, and FR4 = 4.7; with air being an ideal insulator).

Removing segments of the ground plain directly under the input and output pads is recommended.

Outputs of high speed amplifiers are very sensitive to capacitive loads. A capacitive load will introduce a pair of pole and zero to the circuit's frequency response, reducing the phase margin, leading to unstable operation or oscillation.

Generally, it is a good design practice to isolate the amplifier's output from any capacitive load by placing a resistor between the amplifier's output and the rest of the circuits. A series resistor of 10 to 100 ohms is normally sufficient to isolate the output from a capacitive load.

The OP-467 is internally compensated to provide stable operation, and is capable of driving large capacitive loads without oscillation.

Sockets are not recommended since they increase the lead inductance/capacitance and reduce the power dissipation of the package by increasing the leads thermal resistance. If sockets must be used, use Teflon* or pin sockets with the shortest leads possible.

PHASE REVERSAL

The OP-467 is immune to phase reversal; its inputs can exceed the supply rails by a diode drop without any phase reversal.

*Teflon is a registered trademark of E.I. du Pont Co.

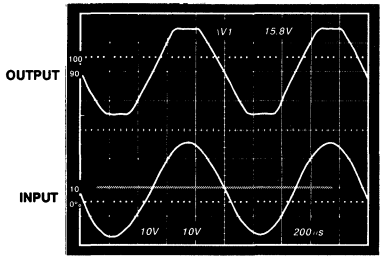

Figure 36. No Phase Reversal (A_V = +1)

SATURATION RECOVERY TIME

The OP-467 has a fast and symmetrical recovery time from either rail. This feature is very useful in applications such as high speed instrumentation and measurement circuits, where the amplifier is frequently exposed to large signals that overload the amplifier.

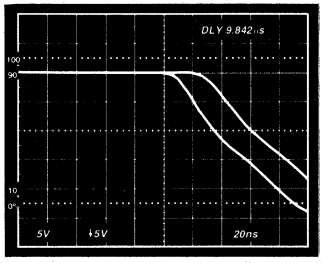

Figure 37. Saturation Recovery Time, Positive Rail

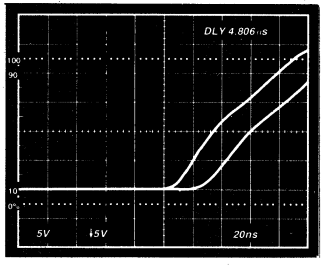

Figure 38. Saturation Recovery Time, Negative Rail

HIGH SPEED INSTRUMENTATION AMPLIFIER

The OP-467 performance lends itself to a variety of high speed applications, including high speed precision instrumentation amplifiers. Figure 39 represents a circuit commonly used for data acquisition, CCD imaging, and other high speed application.

Circuit gain is set by R_G. A 2 kΩ resistor will set the circuit gain to 2, for unity gain, remove R_G. For any other gain settings use the following formula:

$$G = 2/R_G \quad \textit{Resistor Value is in k}\Omega$$

R_C is used for adjusting the dc common-mode rejection, and C_C is used for ac common-mode rejection adjustments.

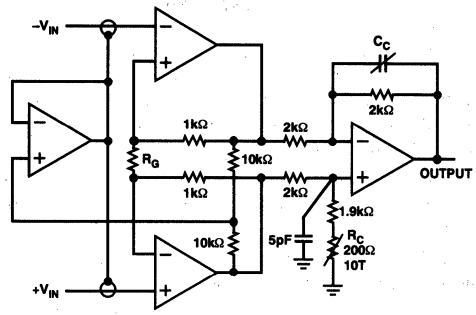

Figure 39. A High Speed Instrumentation Amplifier

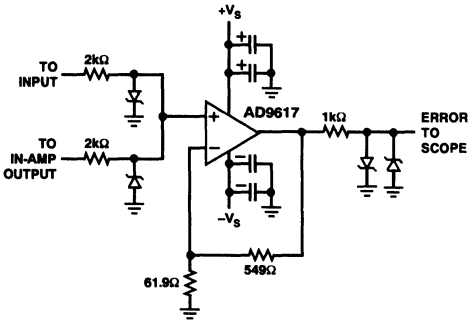

Figure 42. Settling Time Measurement Circuit

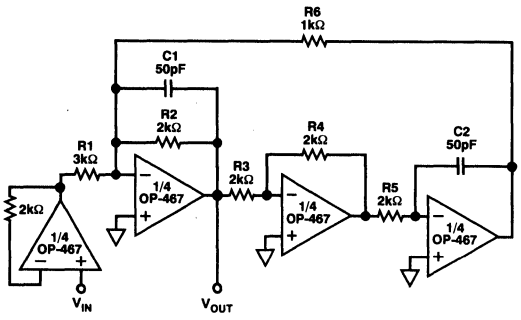

Figure 43. 2 MHz Biquad Filter

2 MHz BIQUAD BANDPASS FILTER

The circuit in Figure 43 is commonly used in medical imaging ultrasound receivers. The 30 MHz bandwidth is sufficient to accurately produce the 2 MHz center frequency, as the measured response shows in Figure 44. When the op amp's bandwidth is too close to the filter's center frequency, the amplifier's internal phase shift causes excess phase shift at 2 MHz, which alters the filter's response. In fact, if the chosen op amp has a bandwidth close to 2 MHz, the combined phase shift of the three op amps will cause the loop to oscillate.

Careful consideration must be given to the layout of this circuit as with any other high speed circuit.

If the phase shift introduced by the layout is large enough, it could alter the circuit performance, or worse, it will oscillate.

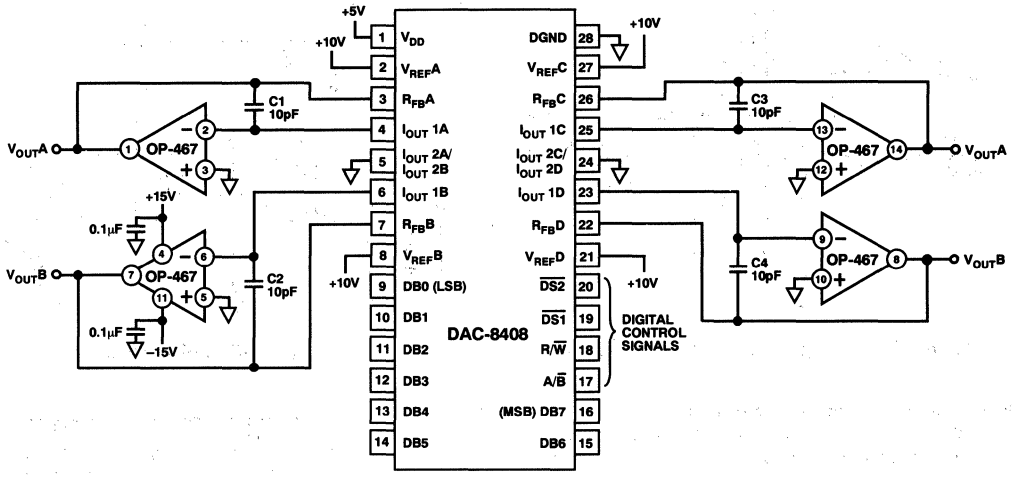

Figure 45. Quad DAC Unipolar Operation

FAST I-TO-V CONVERTER

The fast slew rate and fast settling time of the OP-467 are well suited to the fast buffers and I-to-V converters used in variety of applications. The circuit in Figure 45 is a unipolar quad D/A converter consisting of only two ICs. The current output of the DAC-8408 is converted to a voltage by the OP-467 configured as an I-to-V converter. This circuit is capable of settling to 0.1% within 200 ns. Figures 46 and 47 show the full-scale settling time of the outputs. To obtain reliable circuit performance, keep the traces from the DAC's I_{OUT} to the inverting inputs of the OP-467 short to minimize parasitic capacitance.

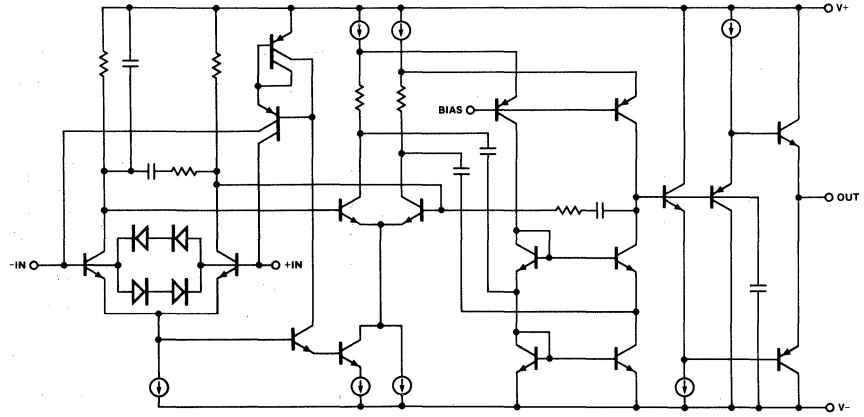
GENERAL DESCRIPTION

The OP-470 is a high-performance monolithic quad operational amplifier with exceptionally low voltage noise, 5nV/$\sqrt{Hz}$ at 1kHz Max, offering comparable performance to PMI's industry standard OP-27.

The OP-470 features an input offset voltage below 0.4mV, excellent for a quad op amp, and an offset drift under 2μV/°C, guaranteed over the full military temperature range. Open-loop gain of the OP-470 is over 1,000,000 into a 10kΩ load insuring excellent gain accuracy and linearity, even in high-gain applications. Input bias current is under 25nA which reduces errors due to signal source resistance. The OP-470's CMR of over 110dB and PSRR of less than 1.8μV/V significantly reduce errors due to ground noise and power supply fluctuations. Power consumption of the quad OP-470 is half that of four OP-27s, a significant advantage for power con-

SIMPLIFIED SCHEMATIC



This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

scious applications. The OP-470 is unity-gain stable with a gain-bandwidth product of 6MHz and a slew rate of 2V/μs.

The OP-470 offers excellent amplifier matching which is important for applications such as multiple gain blocks, low-noise instrumentation amplifiers, quad buffers, and low-noise active filters.

The OP-470 conforms to the industry standard 14-pin DIP pinout. It is pin compatible with the OP-11, LM148/149, HA4741, HA5104, and RM4156 quad op amps and can be used to upgrade systems using these devices.

For higher speed applications the OP-471, with a slew rate of 8V/μs, is recommended.

Low-Voltage Micropower Quad Operational Amplifier

OP490

FEATURES

- Single/Dual Supply Operation ..... +1.6V to +36V
  ..... ±0.8V to ±18V
- True Single-Supply Operation; Input and Output Voltage Ranges Include Ground
- Low Supply Current ..... 80µA Max
- High Output Drive ..... 5mA Min
- Low Offset Voltage ..... 0.5mA Max
- High Open-Loop Gain ..... 700V/mV Min
- Outstanding PSRR ..... 5.6µV/V Min
- Industry Standard Quad Pinouts
- Available in Die Form

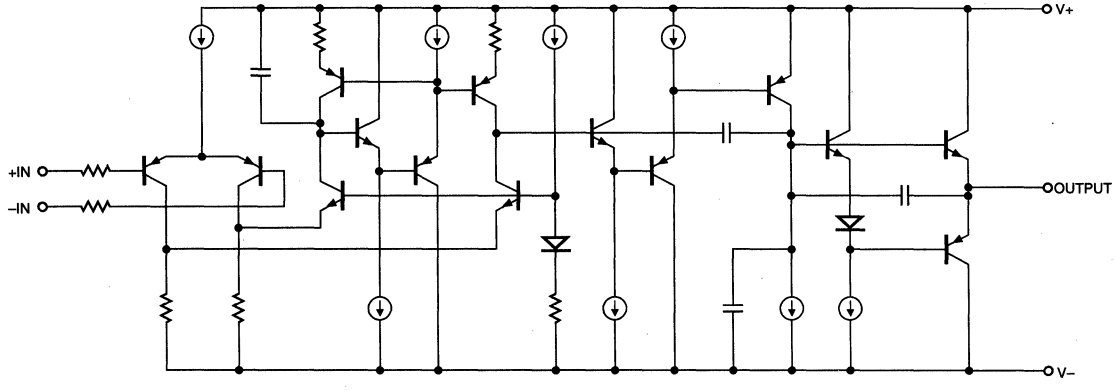
GENERAL DESCRIPTION

The OP-490 is a high-performance micropower quad op amp that operates from a single supply of +1.6V to +36V or from dual supplies of ±0.8V to ±18V. Input voltage range includes the negative rail allowing the OP-490 to accommodate input signals down to ground in single-supply operation. The OP-490's output swing also includes ground when operating from a single supply, enabling "zero-in, zero-out" operation.

Continued

SIMPLIFIED SCHEMATIC (One of four amplifiers is shown.)



This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

GENERAL DESCRIPTION *Continued*

The quad OP-490 draws less than 20μA of quiescent supply current per amplifier, but each amplifier is able to deliver over 5mA of output current to a load. Input offset voltage is under 0.5mV with offset drift below 5μV/°C over the military temperature range. Gain exceeds over 700,000 and CMR is better than 100dB. A PSRR of under 5.6μV/V minimizes offset voltage changes experienced in battery powered systems.

The quad OP-490 combines high performance with the space and cost savings of quad amplifiers. The minimal voltage and current requirements of the OP-490 makes it ideal for battery and solar powered applications, such as portable instruments and remote sensors.

ABSOLUTE MAXIMUM RATINGS (Note 2)

Supply Voltage ..... ±18V
Differential Input Voltage ..... [(V–) – 20V] to [(V+) + 20V]
Common-Mode Input Voltage ..... [(V–) – 20V] to [(V+) + 20V]
Output Short-Circuit Duration ..... Continuous

Storage Temperature Range
TC, Y, P Package ..... –65°C to +150°C
Operating Temperature Range

Precision Picoampere Input Current Quad Operational Amplifier

OP497

FEATURES

Low Offset Voltage: 50 μV max
Low Offset Voltage Drift: 0.5 μV/°C max
Very Low Bias Current
+25°C: 100 pA max
−55°C to +125°C: 450 pA max
Very High Open-Loop Gain: 2000 V/mV min
Low Supply Current (per Amplifier): 625 μA max
Operates from ±2 V to ±20 V Supplies
High Common-Mode Rejection: 120 dB min

APPLICATIONS

Strain Gage and Bridge Amplifiers
High Stability Thermocouple Amplifiers
Instrumentation Amplifiers
Photo-Current Monitors
High-Gain Linearity Amplifiers
Long-Term Integrators/Filters
Sample-and-Hold Amplifiers
Peak Detectors
Logarithmic Amplifiers
Battery-Powered Systems

GENERAL DESCRIPTION

The OP-497 is a quad op amp with precision performance in the space saving, industry standard 16-pin SOIC package. Its combination of exceptional precision with low power and extremely low input bias current makes the quad OP-497 useful in a wide variety of applications.

Precision performance of the OP-497 includes very low offset, under 50 μV, and low drift, below 0.5 μV/°C. Open-loop gain exceeds 2000 V/mV insuring high linearity in every application. Errors due to common-mode signals are eliminated by the OP-497's common-mode rejection of over 120 dB. The OP-497's power supply rejection of over 120 dB minimizes offset voltage changes experienced in battery powered systems. Supply current of the OP-497 is under 625 μA per amplifier, and it can operate with supply voltages as low as ±2 V.

The OP-497 utilizes a superbeta input stage with bias current cancellation to maintain picoamp bias currents at all temperatures. This is in contrast to FET input op amps whose bias currents start in the picoamp range at 25°C, but double for every 10°C rise in temperature, to reach the nanoamp range above 85°C. Input bias current of the OP-497 is under 100 pA at 25°C and is under 450 pA over the military temperature range.

Combining precision, low power and low bias current, the OP-497 is ideal for a number of applications including instrumentation amplifiers, log amplifiers, photo-diode preamplifiers and long term integrators. For a single device see the OP-97, for a dual see the OP-297.

NOTE
[1]Guaranteed by CMR Test.
Specifications subject to change without notice.

WAFER TEST LIMITS (@ V_S = ±15 V, T_A = +25°C, unless otherwise noted)

Parameter	Symbol	Condition	OP-497 GBC Limit	Units
Input Offset Voltage	V_{OS}		150	μV max
Input Offset Current	I_{OS}	V_{CM} = 0 V	150	pA max
Input Bias Current	I_B	V_{CM} = 0 V	150	pA max
Input Voltage Range[1]	IVR		±13	V min
Large Signal Voltage Gain	A_{VO}	V_O = ±10 V, $R_L \leq$ 10 kΩ	1500	V/mV min
Common-Mode Rejection	CMR	V_{CM} = ±13 V	114	dB min
Power Supply Rejection	PSR	V_S = ±2 V to ±20 V	114	dB min
Output Voltage Swing	V_O	$R_L \leq$ 10 kΩ	±13	V min
		$R_L \leq$ 2 kΩ	±13	V min
Supply Current per Amplifier	I_{SY}	No Load	625	μA max

NOTE
[1]Guaranteed by CMR test. Electrical tests are performed at wafer probe to the limits shown. Due to variations in assembly methods and normal yield loss, yield after packaging is not guaranteed for standard product dice. Consult factory to negotiate specifications based on dice lot qualifications through sample lot assembly and testing.

ANALOG DEVICES

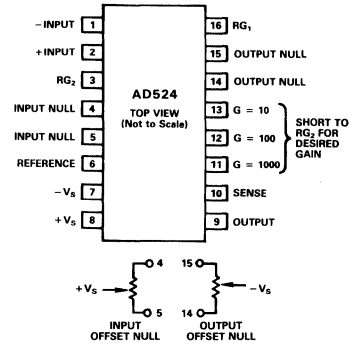
Precision Instrumentation Amplifier

AD524

FEATURES

Low Noise: 0.3μV p-p 0.1Hz to 10Hz
Low Nonlinearity: 0.003% (G = 1)
High CMRR: 120dB (G = 1000)
Low Offset Voltage: 50μV
Low Offset Voltage Drift: 0.5μV/°C
Gain Bandwidth Product: 25MHz
Pin Programmable Gains of 1, 10, 100, 1000
Input Protection, Power On – Power Off
No External Components Required
Internally Compensated
MIL-STD-883B and Chips Available
16-Pin Ceramic DIP and SOIC Packages and 20-Terminal Leadless Chip Carriers Available
Available in Tape and Reel in Accordance with EIA-481A Standard
Standard Military Drawing Also Available

CONNECTION DIAGRAMS
Ceramic (D) and SOIC (R) Packages



Leadless Chip Carrier (E) Package

PRODUCT DESCRIPTION

The AD524 is a precision monolithic instrumentation amplifier designed for data acquisition applications requiring high accuracy under worst-case operating conditions. An outstanding combination of high linearity, high common mode rejection, low offset voltage drift, and low noise makes the AD524 suitable for use in many data acquisition systems.

The AD524 has an output offset voltage drift of less than 25μV/°C, input offset voltage drift of less than 0.5μV/°C, CMR above 90dB at unity gain (120dB at G = 1000) and maximum nonlinearity of 0.003% at G = 1. In addition to the outstanding dc specifications the AD524 also has a 25MHz gain bandwidth product (G = 100). To make it suitable for high speed data acquisition systems the AD524 has an output slew rate of 5V/μs and settles in 15μs to 0.01% for gains of 1 to 100.

As a complete amplifier the AD524 does not require any external components for fixed gains of 1, 10, 100 and 1,000. For other gain settings between 1 and 1000 only a single resistor is required. The AD524 input is fully protected for both power on and power off fault conditions.

The AD524 IC instrumentation amplifier is available in four different versions of accuracy and operating temperature range. The economical "A" grade, the low drift "B" grade and lower drift, higher linearity "C" grade are specified from −25°C to +85°C. The "S" grade guarantees performance to specification over the extended temperature range −55°C to +125°C. Devices are available in 16-pin ceramic DIP and SOIC packages and a 20-terminal leadless chip carrier.

PRODUCT HIGHLIGHTS

1. The AD524 has guaranteed low offset voltage, offset voltage drift and low noise for precision high gain applications.
2. The AD524 is functionally complete with pin programmable gains of 1, 10, 100 and 1000, and single resistor programmable for any gain.
3. Input and output offset nulling terminals are provided for very high precision applications and to minimize offset voltage changes in gain ranging applications.
4. The AD524 is input protected for both power on and power off fault conditions.
5. The AD524 offers superior dynamic performance with a gain bandwidth product of 25MHz, full power response of 75kHz and a settling time of 15μs to 0.01% of a 20V step (G = 100).

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

NOTES
[1]Does not include effects of external resistor R_G.
[2]V_{OL} is the maximum differential input voltage at G = 1 for specified nonlinearity.
V_{DL} at other gains = 10V/G.
V_D = Actual differential input voltage.
Example: G = 10, V_D = 0.50
V_{CM} = 12V − (10/2 × 0.50V) = 9.5V
Specifications subject to change without notice.
All min and max specifications are guaranteed. Specifications shown in **boldface** are tested on all production units at final electrical test. Results from those tests are used to calculate outgoing quality levels.

ABSOLUTE MAXIMUM RATINGS[1]

Supply Voltage . . . . . ±18V
Internal Power Dissipation 450mW
Input Voltage,[2]
(Either Input Simultaneously) $|V_{IN}| + |V_S|$ . . . . . <36V
Output Short Circuit Duration . . . . . Indefinite
Storage Temperature Range
(R) . . . . . −65°C to +125°C
(D, E) . . . . . −65°C to +150°C
Operating Temperature Range
AD524A/B/C . . . . . −25°C to +85°C
AD524S . . . . . −55°C to +125°C
Lead Temperature Range (Soldering 60 seconds) . . +300°C

NOTES
[1]Stresses above those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. This is a stress rating only and functional operation of the device at these or any other conditions above those indicated in the operational section of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.
[2]Max input voltage specification refers to maximum voltage to which either input terminal may be raised with or without device power applied. For example, with ±18 volt supplies max V_{IN} is ±18 volts, with zero supply voltage max V_{IN} is ±36 volts.

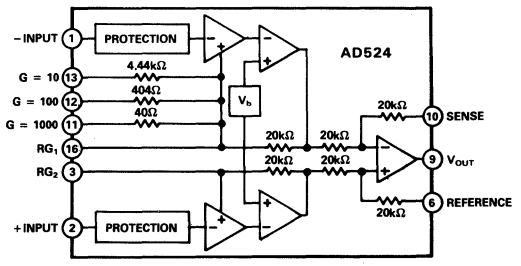
FUNCTIONAL BLOCK DIAGRAM



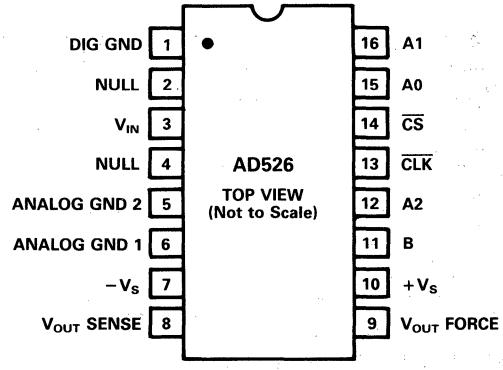
Software Programmable Gain Amplifier

AD526

FEATURES

Digitally Programmable Binary Gains from 1 to 16
Two-Chip Cascade Mode Achieves Binary Gain from 1 to 256
Gain Error:
0.01% max, Gain = 1, 2, 4 (C Grade)
0.02% max, Gain = 8, 16 (C Grade)
0.5ppm/°C Drift Over Temperature
Fast Settling Time
10V Signal Change:
0.01% in 4.5μs (Gain = 16)
Gain Change:
0.01% in 5.6μs (Gain = 16)
Low Nonlinearity: ±0.005% FSR max (J Grade)
Excellent DC Accuracy:
Offset Voltage: 0.5mV max (C Grade)
Offset Voltage Drift: 3μV/°C (C Grade)
TTL Compatible Digital Inputs
Standard Military Drawing Available

PIN CONFIGURATION



PRODUCT DESCRIPTION

The AD526 is a single-ended, monolithic software programmable gain amplifier (SPGA) that provides gains of 1, 2, 4, 8 and 16. It is complete, including amplifier, resistor network and TTL-compatible latched inputs, and requires no external components.

Low gain error and low nonlinearity make the AD526 ideal for precision instrumentation applications requiring programmable gain. The small signal bandwidth is 350kHz at a gain of 16. In addition, the AD526 provides excellent dc precision. The FET-input stage results in a low bias current of 50pA. A guaranteed maximum input offset voltage of 0.5mV max (C grade) and low gain error (0.01%, G=1, 2, 4, C grade) are accomplished using Analog Devices' laser trimming technology.

To provide flexibility to the system designer, the AD526 can be operated in either latched or transparent mode. The force/sense configuration preserves accuracy when the output is connected to remote or low impedance loads.

The AD526 is offered in one commercial (0 to +70°C) grade, J, and three industrial grades, A, B and C, which are specified from −40°C to +85°C. The S grade is specified from −55°C to +125°C. The military version is available processed to MIL-STD 883B, Rev C. The J grade is supplied in a 16-pin plastic DIP, and the other grades are offered in a 16-pin hermetic side-brazed ceramic DIP.

APPLICATION HIGHLIGHTS

1. **Dynamic Range Extension for ADC Systems:** A single AD526 in conjunction with a 12-bit ADC can provide 96dB of dynamic range for ADC systems.
2. **Gain Ranging Pre-Amps:** The AD526 offers complete digital gain control with precise gains in binary steps from 1 to 16. Additional gains of 32, 64, 128 and 256 are possible by cascading two AD526s.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

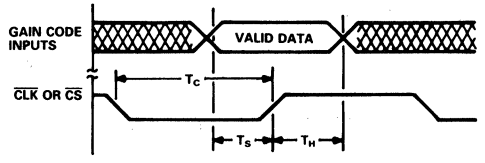

Figure 35. AD526 Timing

Low Cost, Low Power Instrumentation Amplifier

AD620

FEATURES
EASY TO USE
Gain Set with One External Resistor (Gain Range 1 to 1000)
Wide Power Supply Range (±2.3 V to ±18 V)
Higher Performance than Three Op Amp IA Designs
Available in 8-Pin DIP and SOIC Packaging
Low Power, 1.3 mA max Supply Current

EXCELLENT DC PERFORMANCE ("A GRADE")
125 μV max, Input Offset Voltage (50 μV max "B" Grade)
1 μV/°C max, Input Offset Drift
2.0 nA max, Input Bias Current
93 dB min Common-Mode Rejection Ratio (G = 10)

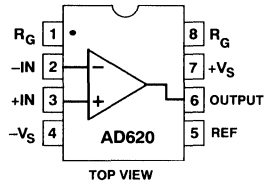
LOW NOISE
9 nV/√Hz, @ 1 kHz, Input Voltage Noise
0.28 μV p-p Noise (0.1 Hz to 10 Hz)

EXCELLENT AC SPECIFICATIONS
120 kHz Bandwidth (G = 100)
15 μs Settling Time to 0.01%

APPLICATIONS
Weigh Scales
ECG and Medical Instrumentation
Transducer Interface
Data Acquisition Systems
Industrial Process Controls
Battery Powered and Portable Equipment

CONNECTION DIAGRAM

8-Pin Plastic Mini-DIP (N), Cerdip (Q) and SOIC (R) Packages

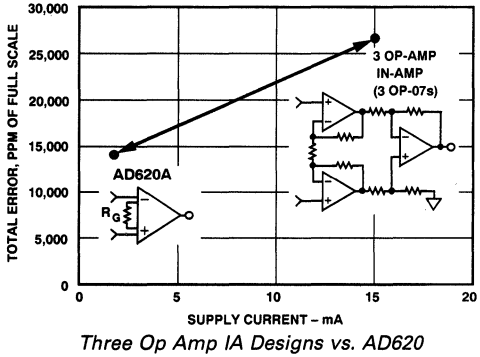


PRODUCT DESCRIPTION

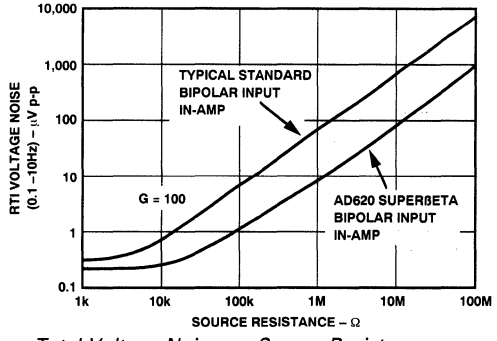
The AD620 is a low cost, high accuracy instrumentation amplifier which requires only one external resistor to set gains of 1 to 1000. Furthermore, the AD620 features 8-pin SOIC and DIP packaging that is smaller than discrete designs, and offers lower power (only 1.3 mA max supply current), making it a good fit for battery powered, portable (or remote) applications.

The AD620, with its high accuracy of 40 ppm maximum nonlinearity, low offset voltage of 50 μV max and offset drift of 0.6 μV/°C max, is ideal for use in precision data acquisition systems, such as weigh scales and transducer interfaces. Furthermore, the low noise, low input bias current, and low power of the AD620 make it well suited for medical applications such as ECG and noninvasive blood pressure monitors.

The low input bias current of 1.0 nA max is made possible with the use of Superβeta processing in the input stage. The AD620 works well as a preamplifier due to its low input voltage noise of 9 nV/√Hz at 1 kHz, 0.28 μV p-p in the 0.1 Hz to 10 Hz band, 0.1 pA/√Hz input current noise. Also, the AD620 is well suited for multiplexed applications with its settling time of 15 μs to 0.01% and its cost is low enough to enable designs with one in amp per channel.



Three Op Amp IA Designs vs. AD620



Total Voltage Noise vs. Source Resistance

(Soldering 10 seconds) . . . . . 300°C

NOTES
[1]Stresses above those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. This is a stress rating only and functional operation of the device at these or any other conditions above those indicated in the operational section of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.
[2]Specification is for device in free air:
8-Pin Plastic Package: θ_{JA} = 95°C/Watt
8-Pin Cerdip Package: θ_{JA} = 110°C/Watt
8-Pin SOIC Package: θ_{JA} = 155°C/Watt

ORDERING GUIDE

Model	Temperature Range	Package Option*
AD620AN	−40°C to +85°C	N-8
AD620BN	−40°C to +85°C	N-8
AD620AR	−40°C to +85°C	R-8
AD620BR	−40°C to +85°C	R-8
AD620AChips	−40°C to +85°C	Die Form
AD620SQ/883B	−55°C to +125°C	Q-8

*N = Plastic DIP; Q = Cerdip; R = SOIC.

ESD SUSCEPTIBILITY

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 volts, which readily accumulate on the human body and on test equipment, can discharge without detection. Although the AD620 features proprietary ESD protection circuitry, permanent damage may still occur on these devices if they are subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid any performance degradation or loss of functionality.

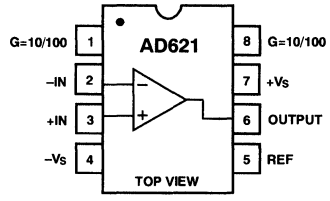
Low Drift, Low Power Instrumentation Amplifier

AD621

FEATURES
EASY TO USE
Pin-Strappable Gains of 10 & 100
All Errors Specified for Total System Performance
Higher Performance than Discrete In-Amp Designs
Available in 8-Pin DIP and SOIC
Low Power, 1.3 mA max Supply Current
Wide Power Supply Range (±2.3 V to ±18 V)
EXCELLENT DC PERFORMANCE
0.15% max, Total Gain Error
±5 ppm/°C, Total Gain Drift
125 μV max, Total Offset Voltage
1.0 μV/°C max, Offset Voltage Drift
LOW NOISE
9 nV/√Hz, @ 1 kHz, Input Voltage Noise
0.28 μV p–p Noise (0.1 Hz to 10 Hz)
EXCELLENT AC SPECIFICATIONS
800 kHz Bandwidth (G = 10), 200 kHz (G = 100)
12 μs Settling Time to 0.01%
APPLICATIONS
Weigh Scales
Transducer Interface & Data Acquisition Systems
Industrial Process Controls
Battery Powered and Portable Equipment

CONNECTION DIAGRAM

8-Pin Plastic Mini-DIP (N), Cerdip (Q) and SOIC (R) Packages

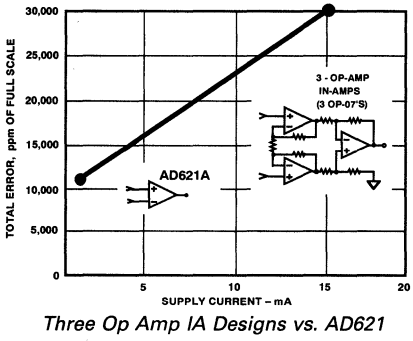


PRODUCT DESCRIPTION

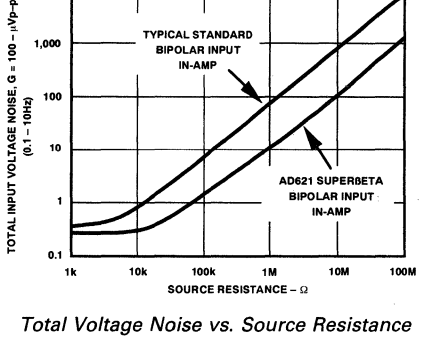
The AD621 is an easy to use, low cost, low power, high accuracy instrumentation amplifier which is ideally suited for a wide range of applications. Its unique combination of high performance, small size and low power, outperforms discrete in amp implementations. High functionality, low gain errors and low gain drift errors are achieved by the use of internal gain setting resistors. Fixed gains of 10 and 100 can be easily set via external pin strapping. The AD621 is fully specified as a total system, therefore, simplifying the design process.

For portable or remote applications, where power dissipation, size and weight are critical, the AD621 features a very low supply current of 1.3 mA max and is packaged in a compact 8-pin SOIC, 8-pin plastic DIP or 8-pin cerdip. The AD621 also excels in applications requiring high total accuracy, such as precision data acquisition systems used in weigh scales and transducer interface circuits. Low maximum error specifications including nonlinearity of 10 ppm, gain drift of 5 ppm/°C, 50 μV offset voltage and 0.6 μV/°C offset drift ("B" grade), make possible total system performance at a lower cost than has been previously achieved with discrete designs or with other monolithic instrumentation amplifiers.

When operating from high source impedances, as in ECG and blood pressure monitors, the AD621 features the ideal combination of low noise and low input bias currents. Voltage noise is specified as 9 nV/√Hz at 1 kHz and 0.28 μV p–p from 0.1 Hz to 10 Hz. Input current noise is also extremely low at 0.1 pA/√Hz. The AD621 outperforms FET input devices with an input bias current specification of 1.5 nA max over the full industrial temperature range.



Three Op Amp IA Designs vs. AD621



Total Voltage Noise vs. Source Resistance

ESD SUSCEPTIBILITY

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 volts, which readily accumulate on the human body and on test equipment, can discharge without detection. Although the AD621 features proprietary ESD protection circuitry, permanent damage may still occur on these devices if they are subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid any performance degradation or loss of functionality.

ANALOG DEVICES

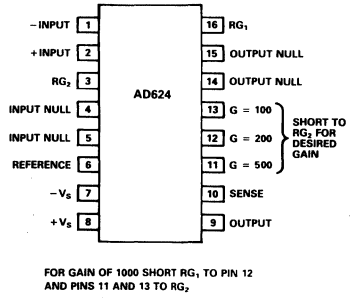
Precision Instrumentation Amplifier

AD624

FEATURES

Low Noise: 0.2μV p-p 0.1Hz to 10Hz
Low Gain TC: 5ppm max (G = 1)
Low Nonlinearity: 0.001% max (G = 1 to 200)
High CMRR: 130dB min (G = 500 to 1000)
Low Input Offset Voltage: 25μV, max
Low Input Offset Voltage Drift: 0.25μV/°C max
Gain Bandwidth Product: 25MHz
Pin Programmable Gains of 1, 100, 200, 500, 1000
No External Components Required
Internally Compensated

CONNECTION DIAGRAM



FOR GAIN OF 1000 SHORT RG_1 TO PIN 12 AND PINS 11 AND 13 TO RG_2

PRODUCT DESCRIPTION

The AD624 is a high precision, low noise, instrumentation amplifier designed primarily for use with low level transducers, including load cells, strain gauges and pressure transducers. An outstanding combination of low noise, high gain accuracy, low gain temperature coefficient and high linearity make the AD624 ideal for use in high resolution data acquisition systems.

The AD624C has an input offset voltage drift of less than 0.25μV/°C, output offset voltage drift of less than 10μV/°C, CMRR above 80dB at unity gain (130dB at G=500) and a maximum nonlinearity of 0.001% at G=1. In addition to these outstanding dc specifications, the AD624 exhibits superior ac performance as well. A 25MHz gain bandwidth product, 5V/μs slew rate and 15μs settling time permit the use of the AD624 in high speed data acquisition applications.

The AD624 does not need any external components for pre-trimmed gains of 1, 100, 200, 500 and 1000. Additional gains such as 250 and 333 can be programmed within one percent accuracy with external jumpers. A single external resistor can also be used to set the 624's gain to any value in the range of 1 to 10,000.

PRODUCT HIGHLIGHTS

1. The AD624 offers outstanding noise performance. Input noise is typically less than $4nV/\sqrt{Hz}$ at 1kHz.
2. The AD624 is a functionally complete instrumentation amplifier. Pin programmable gains of 1, 100, 200, 500 and 1000 are provided on the chip. Other gains are achieved through the use of a single external resistor.
3. The offset voltage, offset voltage drift, gain accuracy and gain temperature coefficients are guaranteed for all pre-trimmed gains.
4. The AD624 provides totally independent input and output offset nulling terminals for high precision applications. This minimizes the effect of offset voltage in gain ranging applications.
5. A sense terminal is provided to enable the user to minimize the errors induced through long leads. A reference terminal is also provided to permit level shifting at the output.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

Programmable Gain Instrumentation Amplifier

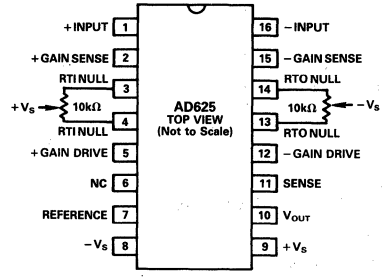
AD625

FEATURES

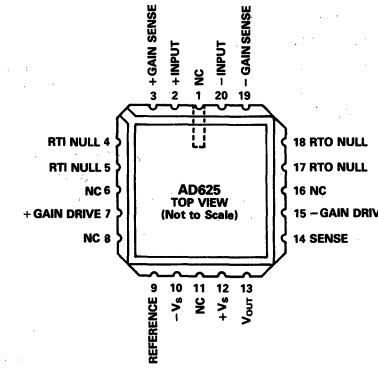
User Programmable Gains of 1 to 10,000
Low Gain Error: 0.02% max
Low Gain TC: 5ppm/°C max
Low Nonlinearity: 0.001% max
Low Offset Voltage: 25μV
Low Noise 4nV/√Hz (at 1kHz) RTI
Gain Bandwidth Product: 25MHz
16-Pin Ceramic or Plastic DIP Package, 20-Pin LCC Package
Standard Military Drawing Available
MIL-Standard Parts Available
Low Cost

CONNECTION DIAGRAMS

Ceramic DIP (D) and Plastic DIP (N) Packages



Leadless Chip Carrier (E) Package



PRODUCT DESCRIPTION

The AD625 is a precision instrumentation amplifier specifically designed to fulfill two major areas of application:
1) Circuits requiring nonstandard gains (i.e., gains not easily achievable with devices such as the AD524 and AD624).
2) Circuits requiring a low cost, precision software programmable gain amplifier.

For low noise, high CMRR, and low drift the AD625JN is the most cost effective instrumentation amplifier solution available. An additional three resistors allow the user to set any gain from 1 to 10,000. The error contribution of the AD625JN is less than 0.05% gain error and under 5ppm/°C gain TC; performance limitations are primarily determined by the external resistors. Common-mode rejection is independent of the feedback resistor matching.

A software programmable gain amplifier (SPGA) can be configured with the addition of a CMOS multiplexer (or other switch network), and a suitable resistor network. Because the ON resistance of the switches is removed from the signal path, an AD625 based SPGA will deliver 12-bit precision, and can be programmed for any set of gains between 1 and 10,000, with completely user selected gain steps.

For the highest precision, the AD625C offers an input offset voltage drift of less than 0.25μV/°C, output offset drift below 15μV/°C, and a maximum nonlinearity of 0.001% at G = 1. All grades exhibit excellent ac performance; a 25MHz gain bandwidth product, 5V/μs slew rate and 15μs settling time.

The AD625 is available in three accuracy grades (A, B, C) for industrial (−40°C to +85°C) temperature range, two grades (J, K) for commercial (0 to +70°C) temperature range, and one (S) grade rated over the extended (−55°C to +125°C) temperature range.

PRODUCT HIGHLIGHTS

1. The AD625 affords up to 16-bit precision for user selected fixed gains from 1 to 10,000. Any gain in this range can be programmed by 3 external resistors.
2. A 12-bit software programmable gain amplifier can be configured using the AD625, a CMOS multiplexer and a resistor network. Unlike previous instrumentation amplifier designs, the ON resistance of a CMOS switch does not affect the gain accuracy.
3. The gain accuracy and gain temperature coefficient of the amplifier circuit are primarily dependent on the user selected external resistors.
4. The AD625 provides totally independent input and output offset nulling terminals for high precision applications. This minimizes the effects of offset voltage in gain-ranging applications.
5. The proprietary design of the AD625 provides input voltage noise of 4nV/√Hz at 1kHz.
6. External resistor matching is not required to maintain high common-mode rejection.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

NOTES

[1]Gain Error and Gain TC are for the AD625 only. Resistor network errors will add to the specified errors.

[2]V_{DL} is the maximum differential input voltage at G = 1 for specified nonlinearity.

V_{DL} at other gains = 10V/G.

V_D = actual differential input voltage.

Example: G = 10, V_D = 0.50

V_{CM} = 12V–(10/2 × 0.50V) = 9.5V.

Specifications subject to change without notice.

All min and max specifications are guaranteed. Specifications shown in **boldface** are tested on all production units at final electrical test. Results from those tests are used to calculate outgoing quality levels.

FEATURES

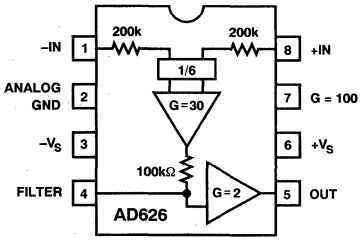
- Pin Selectable Gains of 10 and 100
- True Single Supply Operation
  - Single Supply Range of +2.4 V to +10 V
  - Dual Suppy Range of ±1.2 V to ±6 V
  - Wide Output Voltage Range of 30 mV to 4.7 V
- Optional Low-Pass Filtering
- Excellent DC Performance
  - Low Input Offset Voltage: 500 μV max
  - Large Common-Mode Range: 0 V to +54 V
  - Low Power: 1.2 mW (V_S = +5 V)
  - Good CMR of 90 dB typ
- AC Performance
  - Fast Settling Time: 24 μs (0.01%)
- Includes Input Protection
  - Series Resistive Inputs (R_{IN} = 200 kΩ)
  - RFI Filters Included
  - Allows 50 V Continuous Overload

APPLICATIONS

- Current Sensing
- Interface for Pressure Transducers, Position Indicators, Strain Gages, and Other Low Level Signal Sources

CONNECTION DIAGRAM

8-Pin Plastic Mini-DIP (N) and SOIC (R) Packages



PRODUCT DESCRIPTION

The AD626 is a low cost, true single supply differential amplifier designed for amplifying and low-pass filtering small differential voltages from sources having a large common-mode voltage.

The AD626 can operate from either a single supply of +2.4 V to +10 V, or dual supplies of ±1.2 V to ±6 V. The input common-mode range of this amplifier is equal to 6 ($+V_S$ −1 V) which provides a +24 V CMR while operating from a +5 V supply. Furthermore, the AD626 features a CMR of 90 dB typ.

The amplifier's inputs are protected against continuous overload of up to 50 V, and RFI filters are included in the attenuator network. The output range is +0.03 V to +4.9 V using a +5 V supply. The amplifier provides a preset gain of 10, but gains between 10 to 100 can be easily configured with an external resistor. Furthermore, a gain of 100 is available by connecting the G = 100 pin to analog ground. The AD626 also offers low- pass filter capability by connecting a capacitor between the filter pin and analog ground.

The AD626A and AD626B operate over the industrial temperature range of −40°C to +85°C. The AD626 is available in two 8-pin packages: a plastic mini-DIP and SOIC.

AMP01

GENERAL DESCRIPTION

The AMP-01 is a monolithic instrumentation amplifier designed for high-precision data acquisition and instrumentation applications. The design combines the conventional features of an instrumentation amplifier with a high-current output stage. The output remains stable with high capacitance loads (1μF), a unique ability for an instrumentation amplifier. Consequently, the AMP-01 can amplify low-level signals for transmission through long cables without requiring an output buffer. The output stage may be configured as a voltage or current generator.

Input offset voltage is very low (20μV) which generally eliminates the external null potentiometer. Temperature changes have minimal effect on offset; TCV_{IOS} is typically 0.15μV/°C. Excellent low-frequency noise performance is achieved with a minimal compromise on input protection. Bias current is very low, less than 10nA over the military temperature range. High common-mode rejection of 130dB, 16-bit linearity at a gain of 1000, and 50mA peak output current are achievable simultaneously. This combination takes the instrumentation amplifier one step further towards the ideal amplifier.

AC performance complements the superb DC specifications. The AMP-01 slews at 4.5V/μs into capacitive loads of up to 15nF, settles in 50μs to 0.01% at a gain of 1000, and boasts a healthy 26MHz gain-bandwidth product. These features make the AMP-01 ideal for high-speed data-acquisition systems.

Gain is set by the ratio of two external resistors over a range of 0.1 to 10,000. A very low gain-temperature-coefficient of 10ppm/°C is achievable over the whole gain range. Output voltage swing is guaranteed with three load resistances; 50Ω, 500Ω, and 2kΩ. Loaded with 500Ω, the output delivers ±13.0V minimum. A thermal shutdown circuit prevents destruction of the output transistors during overload conditions.

The AMP-01 can also be configured as a high-performance operational amplifier. In many applications, the AMP-01 can be used in place of op-amp/power-buffer combinations.

THEORY OF OPERATION

An instrumentation amplifier, unlike an op amp, requires precise internal feedback. The two techniques presently in use are resistive and current feedback.

The AMP-01 employs the current feedback approach which has significant advantages over resistive feedback. Advantages of current-feedback are:

a. The technique yields a very high common-mode rejection ratio. The AMP-01 CMR is in excess of 130dB at a gain of 1000.
b. The gain of the current feedback design is set by the ratio of two external resistors. Using external resistors allows any practical gain to be set with high precision and very low gain temperature coefficient.
c. The current-feedback design is immune to CMR degradation when series resistance is added to the reference input. A small (trimmable) offset change results from added resistance, e.g. a printed circuit track.

The AMP-01 utilizes low-drift thin-film resistors to minimize output offset temperature drift. A feedback voltage-to-current converter is employed having high linearity and low noise, particularly at low frequencies. Parameter shifts during packaging are eliminated by a post-assembly trimming technique which electronically adjusts the output offset voltage.

The AMP-01 input transistors Q1 and Q2 feed active loads, yielding stage gain in excess of 4000 (see simplified schematic) The output amplifier, A1, is a two-stage design having a gain of about 50,000 driving a 100Ω load. Overall gain of 2×10^8 yields excellent linearity, even at high closed-loop gains.

Low bias current is achieved by using Ion-implanted superbeta transistors combined with a new bias-current cancellation system, patents applied for. Input bias current remains below 10nA over the military temperature range, −55°C to +125°C.

Superbeta transistors use a new transistor geometry resulting in an input noise of only $5nV/\sqrt{Hz}$ at G = 1000. Noise includes contributions from the gain-setting resistor and internal overload-protection resistor. The input stage achieves an offset voltage drift of less than 0.3μV/°C (E Grade).

The AMP-01 uses a unique two-pole compensation scheme where the load capacitance is incorporated into the dominate pole. Stable operation results even with high capacitance loads. The high output current capability (90mA peak) allows the 4.5V/μs slew-rate to be maintained with load capacitance as high as 15nF.

ABSOLUTE MAXIMUM RATINGS (Note 1)

Supply Voltage ..... ±18V
Common-Mode Input Voltage ..... Supply Voltage

ANALOG DEVICES

High Accuracy 8-Pin Instrumentation Amplifier

AMP02

FEATURES

- Low Offset Voltage ..... 100μV Max
- Low Drift ..... 2μV/°C Max
- Wide Gain Range ..... 1 to 10,000
- High Common-Mode Rejection ..... 115dB Min
- High Bandwidth (G = 1000) ..... 200kHz Typ
- Gain Equation Accuracy ..... 0.5% Max
- Single Resistor Gain Set
- Input Overvoltage Protection
- Low Cost
- Available In Die Form

APPLICATIONS

- Differential Amplifier
- Strain Gauge Amplifier
- Thermocouple Amplifier
- RTD Amplifier
- Programmable Gain Instrumentation Amplifier
- Medical Instrumentation
- Data Acquisition Systems

† Burn-in is available on commercial and industrial temperature range parts in CerDIP, plastic DIP, and TO-can packages.

GENERAL DESCRIPTION

The AMP-02 is the first precision instrumentation amplifier available in an 8-pin package. Gain of the AMP-02 is set by a single external resistor, and can range from 1 to 10,000. No gain set resistor is required for unity gain. The AMP-02 includes an input protection network that allows the inputs to be taken 60V beyond either supply rail without damaging the device.

Laser trimming reduces the input offset voltage to under 100μV. Output offset voltage is below 4mV and gain accuracy is better than 0.5% for gain of 1000. PMI's proprietary thin-film resistor process keeps the gain temperature coefficient under 50 ppm/°C.

Due to the AMP-02's design, its bandwidth remains very high over a wide range of gain. Slew rate is over 4V/μs making the AMP-02 ideal for fast data acquisition systems.

A reference pin is provided to allow the output to be referenced to an external DC level. This pin may be used for offset correction or level shifting as required. In the 8-pin package, sense is internally connected to the output.

For an instrumentation amplifier with the highest precision, consult the AMP-01 data sheet. For the highest input impedance and speed, consult the AMP-05 data sheet.

ABSOLUTE MAXIMUM RATINGS

Supply Voltage ..... ±18V
Common-Mode Input Voltage ..... [(V–) – 60V] to [(V+) + 60V]
Differential Input Voltage ..... [(V–) – 60V] to [(V+) + 60V]
Output Short-Circuit Duration ..... Continuous
Operating Temperature Range ..... –40°C to +85°C
Storage Temperature Range ..... –65°C to +150°C
Junction Temperature Range ..... –65°C to +150°C
Lead Temperature (Soldering, 10 sec) ..... +300°C

PACKAGE TYPE	Θ_{JA} (Note 2)	Θ_{JC}	UNITS
8-Pin Plastic DIP (P)	96	37	°C/W
16-Pin SOL (S)	92	27	°C/W

NOTE:
1. Absolute maximum ratings apply to both DICE and packaged parts, unless otherwise noted.
2. Θ_{JA} is specified for worst case mounting conditions, i.e., Θ_{JA} is specified for device in socket for P-DIP package; Θ_{JA} is specified for device soldered to printed circuit board for SOL package.

ELECTRICAL CHARACTERISTICS at $V_S = \pm15V$, $V_{CM} = 0V$, $T_A = +25°C$, unless otherwise noted.

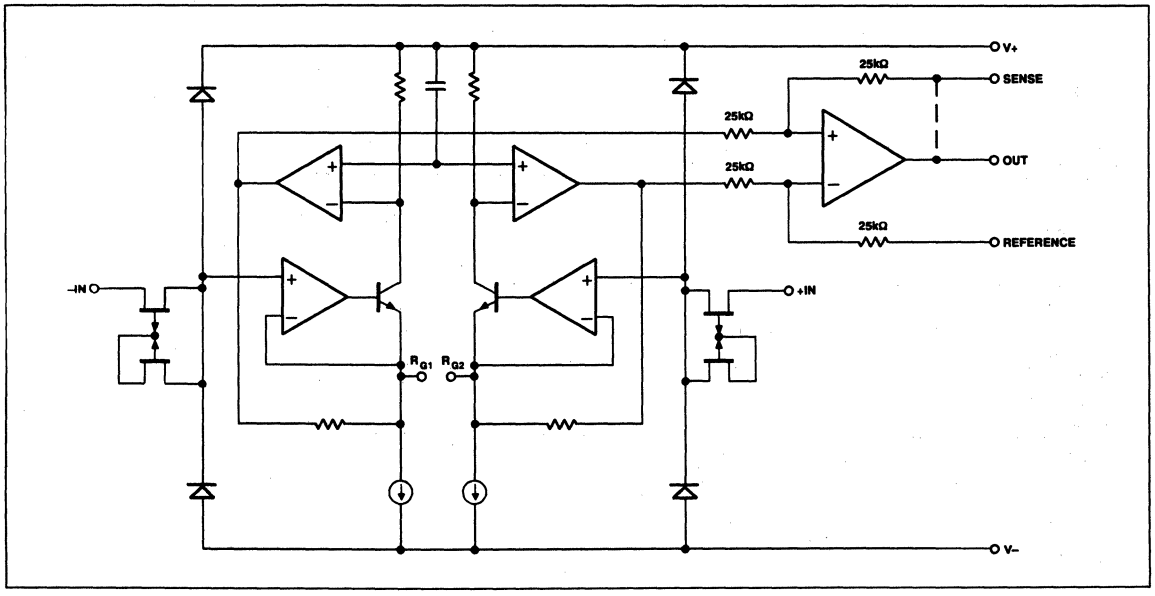
SIMPLIFIED SCHEMATIC



Precision Single Supply Instrumentation Amplifier

AMP04*

FEATURES
Single Supply Operation
Low Supply Current: 700 μA max
Wide Gain Range: 1 to 1000
Low Offset Voltage: 150 μV max
Zero-In/Zero-Out
Single-Resistor Gain Set
8-pin Mini-DIP and SO packages

APPLICATIONS
Strain Gages
Thermocouples
RTDs
Battery Powered Equipment
Medical Instrumentation
Data Acquisition Systems
PC Based Instruments
Portable Instrumentation

GENERAL DESCRIPTION

The AMP-04 is a single-supply instrumentation amplifier designed to work over a +5 volt to ±15 volt supply range. It offers an excellent combination of accuracy, low power consumption, wide input voltage range, and excellent gain performance.

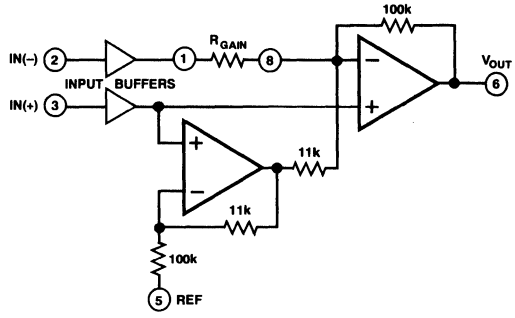
Gain is set by a single external resistor and can be from 1 to 1000. Input common-mode voltage range allows the AMP-04 to handle signals with full accuracy from ground to within 1 volt of the positive supply. And the output can swing to within 1 volt of the positive supply. Gain bandwidth is over 700 kHz. In addition to being easy to use, the AMP-04 draws only 700 μA of supply current.

For high resolution data acquisition systems, laser trimming of low drift thin-film resistors limits the input offset voltage to under 150 μV, and allows the AMP-04 to offer gain nonlinearity of 0.005% and a gain tempco of 30 ppm/°C.

A proprietary input structure limits input offset currents to less than 5 nA with drift of only 8 pA/°C, allowing direct connection of the AMP-04 to high impedance transducers and other signal sources.

*Protected by U.S. Patent No. 5,075,633.

FUNCTIONAL BLOCK DIAGRAM



The AMP-04 is specified over the extended industrial (−40°C to +85°C) temperature range. AMP-04s are available in plastic and ceramic DIP plus SO-8 surface mount packages.

Contact your local sales office for MIL-STD-883 data sheet and availability.

APPLICATIONS

Common-Mode Rejection

The purpose of the instrumentation amplifier is to amplify the difference between the two input signals while ignoring offset and noise voltages common to both inputs. One way of judging the device's ability to reject this offset is the common-mode gain, which is the ratio between a change in the common-mode voltage and the resulting output voltage change. Instrumentation amplifiers are often judged by the common-mode rejection ratio, which is equal to $20 \times \log_{10}$ of the ratio of the user-selected differential signal gain to the common-mode gain, commonly called the CMRR. The AMP-04 offers excellent CMRR, guaranteed to be greater than 90 dB at gains of 100 or greater. Input offsets attain very low temperature drift by proprietary laser-trimmed thin-film resistors and high gain amplifiers.

Input Common-Mode Range Includes Ground

The AMP-04 employs a patented topology (Figure 1) that uniquely allows the common-mode input voltage to truly extend to zero volts where other instrumentation amplifiers fail. To illustrate, take for example the single supply, gain of 100 instrumentation amplifier as in Figure 2. As the inputs approach zero volts, in order for the output to go positive, amplifier A's output (V_{OA}) must be allowed to go below ground, to −0.094 volts. Clearly this is not possible in a single supply environment. Consequently this instrumentation amplifier configuration's input common-mode voltage cannot go below about 0.4 volts. In comparison, the AMP-04 has no such restriction. Its inputs will function with a zero-volt common-mode voltage.

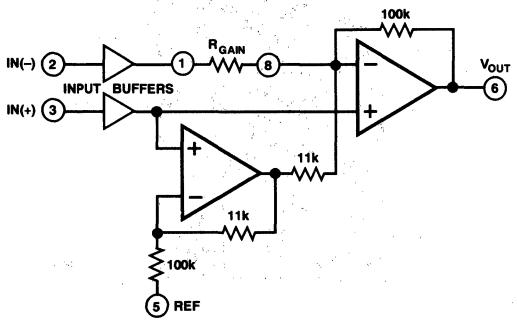

Figure 1. Functional Block Diagram

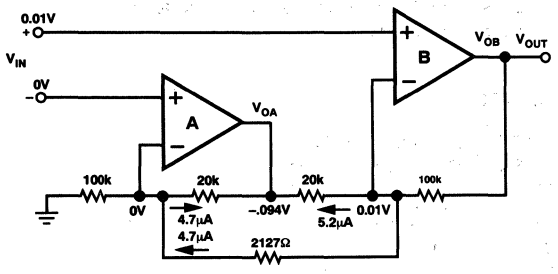

Figure 2. Gain = 100 Instrumentation Amplifier

Input Common-Mode Voltage Below Ground

Although not tested and guaranteed, the AMP-04 inputs are biased in a way that they can amplify signals linearly with common-mode voltage as low as −0.25 volts below ground. This holds true over the industrial temperature range from −40°C to +85°C.

Extended Positive Common-Mode Range

On the high side, other instrumentation amplifier configurations, such as the three op amp instrumentation amplifier, can have severe positive common-mode range limitations. Figure 3 shows an example of a gain of 1001 amplifier, with an input common-mode voltage of 10 volts. For this circuit to function, V_{OB} must swing to 15.01 volts in order for the output to go to 10.01 volts. Clearly no op amp can handle this swing range (given a +15 V supply) as the output will saturate long before it reaches the supply rails. Again the AMP-04's topology does not have this limitation. Figure 4 illustrates the AMP-04 operating at the same common-mode conditions as in Figure 3. None of the internal nodes has a signal high enough to cause amplifier saturation. As a result, the AMP-04 can accommodate much wider common-mode range than most instrumentation amplifiers.

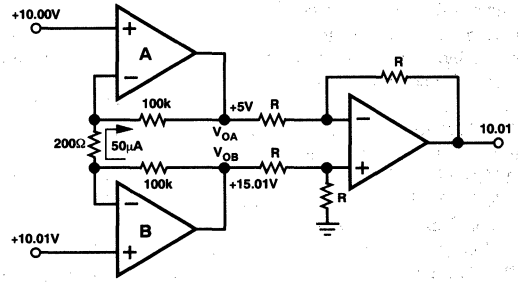

Figure 3. Gain = 1001, Three Op Amp Instrumentation Amplifier

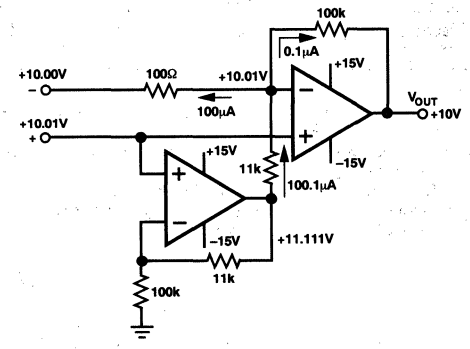

Figure 4. Gain = 1000, AMP-04

Programming the Gain

The gain of the AMP-04 is programmed by the user by selecting a single external resistor—R_{GAIN}:

$$Gain = 100\ k\Omega/R_{GAIN}$$

The output voltage is then defined as the differential input voltage times the gain.

$$V_{OUT} = (V_{IN+} - V_{IN-}) \times \text{Gain}$$

In single supply systems, offsetting the ground is often desired for several reasons. Ground may be offset from zero to provide a quieter signal reference point, or to offset "zero" to allow a unipolar signal range to represent both positive and negative values.

In noisy environments such as those having digital switching, switching power supplies or externally generated noise, ground may not be the ideal place to reference a signal in a high accuracy system.

Often, real world signals such as temperature or pressure may generate voltages that are represented by changes in polarity. In a single supply system the signal input cannot be allowed to go below ground, and therefore the signal must be offset to accommodate this change in polarity. On the AMP-04, a reference input pin is provided to allow offsetting of the input range.

The gain equation is more accurately represented by including this reference input.

$$V_{OUT} = (V_{IN+} - V_{IN-}) \times Gain + V_{REF}$$

Grounding

The most common problems encountered in high performance analog instrumentation and data acquisition system designs are found in the management of offset errors and ground noise. Primarily, the designer must consider temperature differentials and thermocouple effects due to dissimilar metals, IR voltage drops, and the effects of stray capacitance. The problem is greatly compounded when high speed digital circuitry, such as that accompanying data conversion components, is brought into the proximity of the analog section. Considerable noise and error contributions such as fast-moving logic signals that easily propagate into sensitive analog lines, and the unavoidable noise common to digital supply lines must all be dealt with if the accuracy of the carefully designed analog section is to be preserved.

Besides the temperature drift errors encountered in the amplifier, thermal errors due to the supporting discrete components should be evaluated. The use of high quality, low-TC components where appropriate is encouraged. What is more important, large thermal gradients can create not only unexpected changes in component values, but also generate significant thermoelectric voltages due to the interface between dissimilar metals such as lead solder, copper wire, gold socket contacts, Kovar lead frames, etc. Thermocouple voltages developed at these junctions commonly exceed the TCV_{OS} contribution of the AMP-04. Component layout that takes into account the power dissipation at critical locations in the circuit and minimizes gradient effects and differential common-mode voltages by taking advantage of input symmetry will minimize many of these errors.

High accuracy circuitry can experience considerable error contributions due to the coupling of stray voltages into sensitive areas, including high impedance amplifier inputs which benefit from such techniques as ground planes, guard rings, and shields. Careful circuit layout, including good grounding and signal routing practice to minimize stray coupling and ground loops is recommended. Leakage currents can be minimized by using high quality socket and circuit board materials, and by carefully cleaning and coating complete board assemblies.

As mentioned above, the high speed transition noise found in logic circuitry is the sworn enemy of the analog circuit designer. Great care must be taken to maintain separation between them to minimize coupling. A major path for these error voltages will be found in the power supply lines. Low impedance, load related variations and noise levels that are completely acceptable in the high thresholds of the digital domain make the digital supply unusable in nearly all high performance analog applications. The user is encouraged to maintain separate power and ground between the analog and digital systems wherever possible, joining only at the supply itself if necessary, and to observe careful grounding layout and bypass capacitor scheduling in sensitive areas.

Input Shield Drivers

High impedance sources and long cable runs from remote transducers in noisy industrial environments commonly experience significant amounts of noise coupled to the inputs. Both stray capacitance errors and noise coupling from external sources can be minimized by running the input signal through shielded cable. The cable shield is often grounded at the analog input common, however improved dynamic noise rejection and a reduction in effective cable capacitance is achieved by driving the shield with a buffer amplifier at a potential equal to the voltage seen at the input. Driven shields are easily realized with the AMP-04. Examination of the simplified schematic shows that the potentials at the gain set resistor pins of the AMP-04 follow the inputs precisely. As shown in Figure 5, shield drivers are easily realized by buffering the potential at these pins by a dual, single supply op amp such as the OP-213. Alternatively, applications with single-ended sources or that use twisted-pair cable could drive a single shield. To minimize error contributions due to this additional circuitry, all components and wiring should remain in proximity to the AMP-04 and careful grounding and bypassing techniques should be observed.

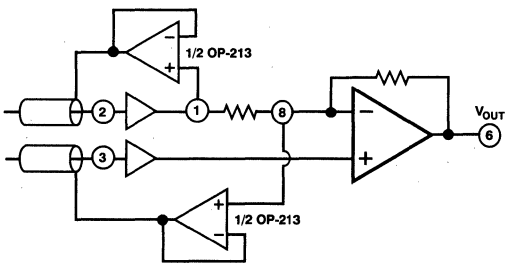

Figure 5. Cable Shield Drivers

Compensating for Input and Output Errors

To achieve optimal performance, the user needs to take into account a number of error sources found in instrumentation amplifiers. These consist primarily of input and output offset voltages and leakage currents.

The input and output offset voltages are independent from one another, and must be considered separately. The input offset component will of course be directly multiplied by the gain of the amplifier, in contrast to the output offset voltage that is independent of gain. Therefore, the output error is the dominant factor at low gains, and the input error grows to become the greater problem as gain is increased. The overall equation for offset voltage error referred to the output (RTO) is:

$$V_{OS}\ (RTO) = (V_{IOS} \times G) + V_{OOS}$$

where V_{IOS} is the input offset voltage and V_{OOS} the output offset voltage, and G is the programmed amplifier gain.

The change in these error voltages with temperature must also be taken into account. The specification TCV_{OS}, referred to the output, is a combination of the input and output drift specifications. Again, the gain influences the input error but not the output, and the equation is:

$$TCV_{OS}\ (RTO) = (TCV_{IOS} \times G) + TCV_{OOS}$$

In some applications the user may wish to define the error contribution as referred to the input, and treat it as an input error. The relationship is:

$$TCV_{OS}\ (RTI) = TCV_{IOS} + (TCV_{OOS} / G)$$

The bias and offset currents of the input transistors also have an impact on the overall accuracy of the input signal. The input leakage, or bias currents of both inputs will generate an additional offset voltage when flowing through the signal source resistance. Changes in this error component due to variations with signal voltage and temperature can be minimized if both input source resistances are equal, reducing the error to a common-mode voltage which can be rejected. The difference in bias current between the inputs, the offset current, generates a differential error voltage across the source resistance that should be taken into account in the user's design.

In applications utilizing floating sources such as thermocouples, transformers, and some photo detectors, the user must take care to provide some current path between the high impedance inputs and analog ground. The input bias currents of the AMP-04, although extremely low, will charge the stray capacitance found in nearby circuit traces, cables, etc., and cause the input to drift erratically or to saturate unless given a bleed path to the analog common. Again, the use of equal resistance values will create a common input error voltage that is rejected by the amplifier.

Reference Input

The V_{REF} input is used to set the system ground. For dual supply operation it can be connected to ground to give zero volts out with zero volts differential input. In single supply systems it could be connected either to the negative supply or to a pseudo-ground between the supplies. In any case, the REF input must be driven with low impedance.

Noise Filtering

Unlike most previous instrumentation amplifiers, the output stage's inverting input (Pin 8) is accessible. By placing a capacitor across the AMP-04's feedback path (Figure 6, Pins 6 and 8)

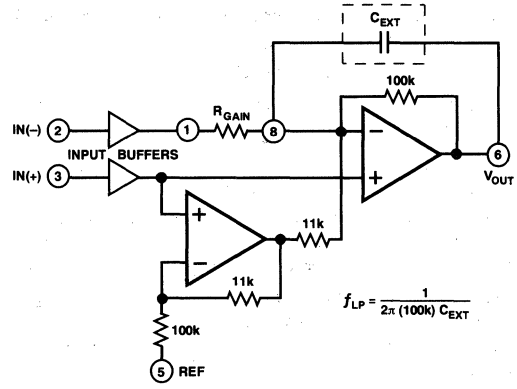

Figure 6. Noise Band Limiting

a single-pole low-pass filter is produced. The cutoff frequency (f_{LP}) follows the relationship:

$$f_{LP} = \frac{1}{2\pi\ (100\ k\Omega)\ C_{ext}}$$

Filtering can be applied to reduce wide band noise. Figure 7a shows a 10 Hz low-pass filter, gain of 1000 for the AMP-04. Figures 7b and 7c illustrate the effect of filtering on noise. The photo in Figure 7b shows the output noise before filtering. By adding a 0.15 μF capacitor, the noise is reduced by about a factor of 4 as shown in Figure 7c.

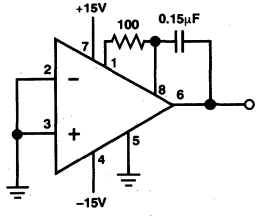

Figure 7a. 10 Hz Low-Pass Filter

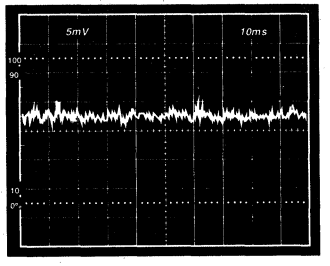

Figure 7b. Unfiltered AMP-04 Output

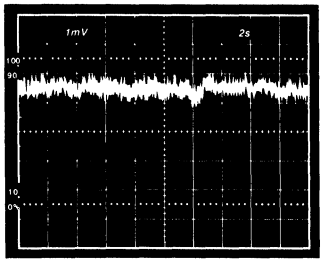

Figure 7c. 10 Hz Low-Pass Filtered Output

Power Supply Considerations
In dual supply applications (for example ±15 V) if the input is connected to a low resistance source less than 100 Ω, a large current may flow in the input leads if the positive supply is applied before the negative supply during power-up. A similar condition may also result upon a loss of the negative supply. If these conditions could be present in you system, it is recommended that a series resistor up to 1 kΩ be added to the input leads to limit the input current.

This condition can not occur in a single supply environment as losing the negative supply effectively removes any current return path.

Offset Nulling in Dual Supply
Offset may be nulled by feeding a correcting voltage at the V_{REF} pin (Pin 5). However, it is important that the pin be driven with a low impedance source. Any measurable resistance will degrade the amplifier's common-mode rejection performance as well as its gain accuracy. An op amp may be used to buffer the offset null circuit as in Figure 8.

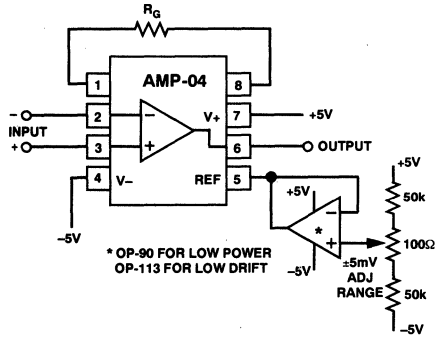

Figure 8. Offset Adjust for Dual Supply Applications

Offset Nulling in Single Supply
Nulling the offset in single supply systems is difficult because the adjustment is made to try to attain zero volts. At zero volts out, the output is in saturation (to the negative rail) and the output voltage is indistinguishable from the normal offset error. Consequently the offset nulling circuit in Figure 9 must be used with caution.

First, the potentiometer should be adjusted to cause the output to swing in the positive direction; then adjust it in the reverse direction, causing the output to swing toward ground, until the output just stops changing. At that point the output is at the saturation limit.

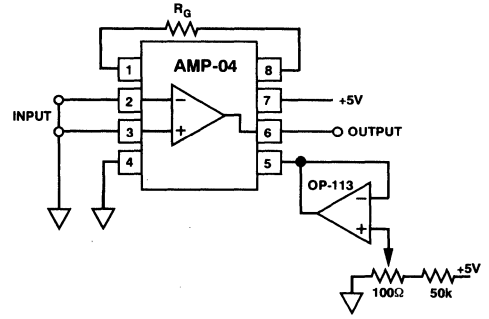

Figure 9. Offset Adjust for Single Supply Applications

Alternative Nulling Method
An alternative null correction technique is to inject an offset current into the summing node of the output amplifier as in Figure 10. This method does not require an external op amp. However the drawback is that the amplifier will move off its null as the input common-mode voltage changes. It is a less desirable nulling circuit than the previous method.

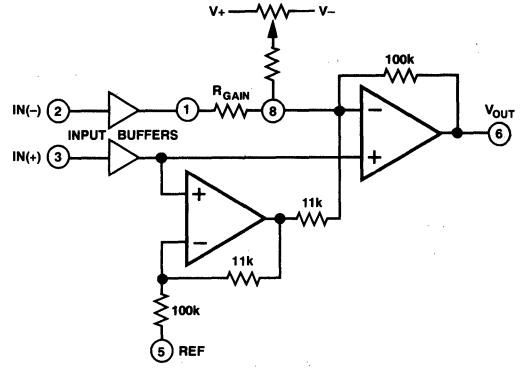

Figure 10. Current Injection Offsetting Is Not Recommended

APPLICATION CIRCUITS

Low Power Precision Single Supply RTD Amplifier

Figure 11 shows a linearized RTD amplifier that is powered off a single +5 volt supply. However, the circuit will work up to 36 volts without modification. The RTD is excited by a 100 μA constant current that is regulated by amplifier A (OP-295). The 0.202 volts reference voltage used to generate the constant current is divided down from the 2.500 volt reference. The AMP-04 amplifies the bridge output to a 10 mV/°C output coefficient.

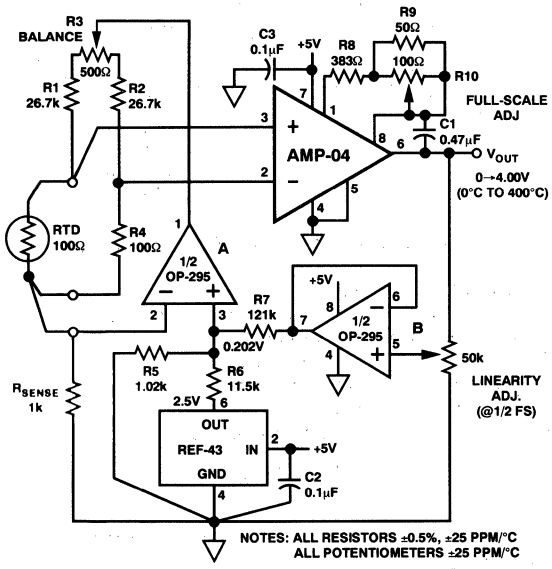

Figure 11. Precision Single Supply RTD Thermometer Amplifier

The RTD is linearized by feeding a portion of the signal back to the reference circuit, increasing the reference voltage as the temperature increases. When calibrated properly, the RTD's nonlinearity error will be canceled.

To calibrate, either immerse the RTD into a zero-degree ice bath or substitute an exact 100 Ω resistor in place of the RTD. Then adjust bridge BALANCE potentiometer R3 for a 0 volt output. Note that a 0 volt output is also the negative output swing limit of the AMP-04 powered with a single supply. Therefore, be sure to adjust R3 to first cause the output to swing positive and then back off until the output just stop swinging negatively.

Next, set the LINEARITY ADJ. potentiometer to the midrange. Substitute an exact 247.04 Ω resistor (equivalent to 400°C temperature) in place of the RTD. Adjust the FULL-SCALE potentiometer for a 4.000 volts output.

Finally substitute a 175.84 Ω resistor (equivalent to 200°C temperature), and adjust the LINEARITY ADJ potentiometer for a 2.000 volts at the output. Repeat the full-scale and the half-scale adjustments as needed.

When properly calibrated, the circuit achieves better than ±0.5°C accuracy within a temperature measurement range from 0°C to 400°C.

Precision 4–20mA Loop Transmitter With Noninteractive Trim

Figure 12 shows a full bridge strain gage transducer amplifier circuit that is powered off the 4–20 mA current loop. The AMP-04 amplifies the bridge signal differentially and is converted to a current by the output amplifier. The total quiescent current drawn by the circuit, which includes the bridge, the amplifiers, and the resistor biasing, is only a fraction of the 4 mA null current that flows through the current-sense resistor R_{SENSE}. The voltage across R_{SENSE} feeds back to the OP-90's input, whose common-mode is fixed at the current summing reference voltage, thus regulating the output current.

With no bridge signal, the 4 mA null is simply set up by the 50 kΩ NULL potentiometer plus the 976 kΩ resistors that inject an offset that forces an 80 mV drop across R_{SENSE}. At a 50 mV full-scale bridge voltage, the AMP-04 amplifies the voltage-to-current converter for a full-scale of 20 mA at the output. Since the OP-90's input operates at a constant 0 volt common-mode voltage, the null and the span adjustments do

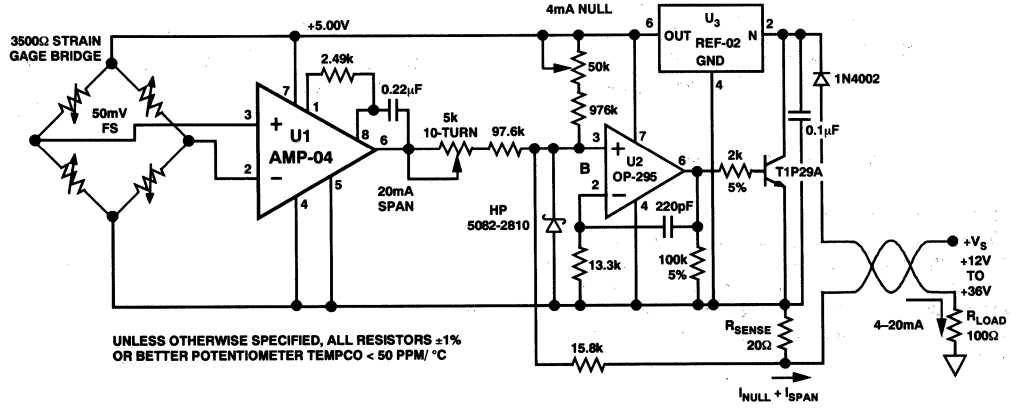

Figure 12. Precision 4–20 mA Loop Transmitter Features Noninteractive Trims

not interact with one another. Calibration is simple and easy with the NULL adjusted first, followed by SPAN adjust. The entire circuit can be remotely placed, and powered from the 4–20 mA 2-wire loop.

4–20 mA Loop Receiver

At the receiving end of a 4–20 mA loop, the AMP-04 makes a convenient differential receiver to convert the current back to a usable voltage (Figure 13). The 4–20 mA signal current passes through a 100 Ω sense resistor. The voltage drop is differentially amplified by the AMP-04. The 4 mA offset is removed by the offset correction circuit.

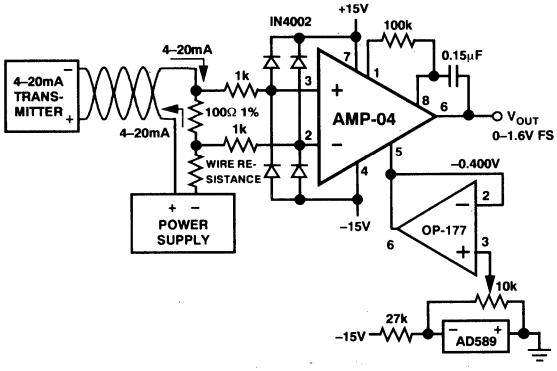

Figure 13. 4 to 20 mA Line Receiver

Low Power, Pulsed Load-Cell Amplifier

Figure 14 shows a 350 Ω load cell that is pulsed with a low duty cycle to conserve power. The OP-295's rail-to-rail output capability allows a maximum voltage of 10 volts to be applied to the bridge. The bridge voltage is selectively pulsed on when a measurement is made. A negative-going pulse lasting 200 ms should be applied to the MEASURE input. The long pulse width is necessary to allow ample settling time for the long time constant of the low-pass filter around the AMP-04. A much faster settling time can be achieved by omitting the filter capacitor.

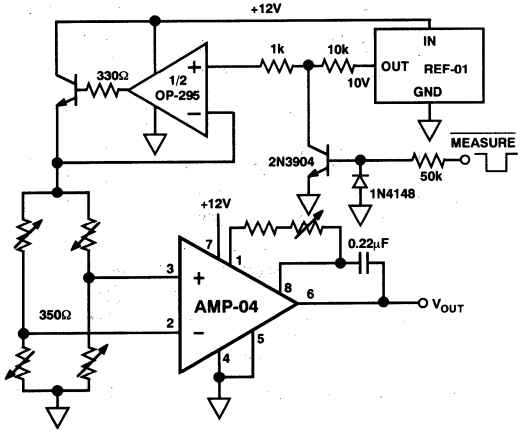

Figure 14. Pulsed Load Cell Bridge Amplifier

Single Supply Programmable Gain Instrumentation Amplifier

Combining with the single supply ADG221 quad analog switch, the AMP-04 makes a useful programmable gain amplifier that can handle input and output signals at zero volts. Figure 15 shows the implementation. A logic low input to any of the gain control ports will cause the gain to change by shorting a gain-set resistor across AMP-04's Pins 1 and 8. Trimming is required at higher gains to improve accuracy because the switch ON-resistance becomes a more significant part of the gain-set resistance. The gain of 500 setting has two switches connected in parallel to reduce the switch resistance.

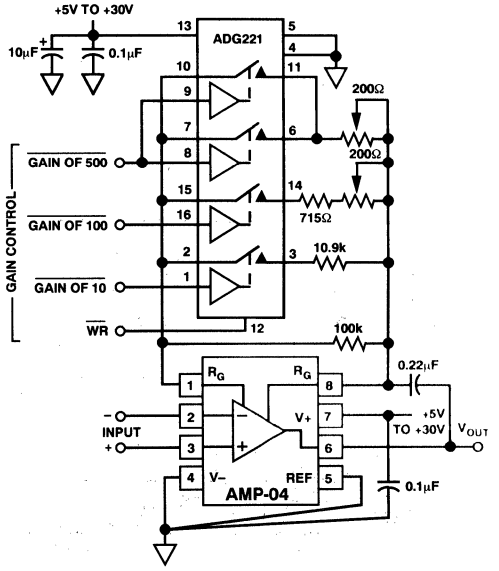

Figure 15. Single Supply Programmable Gain Instrumentation Amplifier

The switch ON resistance is lower if the supply voltage is 12 volts or higher. Additionally the overall amplifier's temperature coefficient also improves with higher supply voltage.

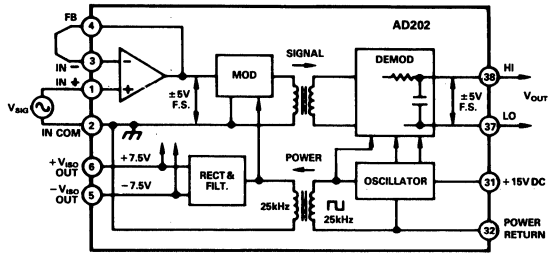
FUNCTIONAL BLOCK DIAGRAM



GENERAL DESCRIPTION

The AD202 and AD204 are general purpose, two-port, transformer-coupled isolation amplifiers that may be used in a broad range of applications where input signals must be measured, processed and/or transmitted without a galvanic connection. These industry standard isolation amplifiers offer a complete isolation function, with both signal and power isolation provided for in a single compact plastic SIP or DIP style package. The primary distinction between the AD202 and the AD204 is that the AD202 is powered directly from a +15V dc supply while the AD204 is powered by an externally supplied clock, such as the recommended AD246 Clock Driver.

The AD202 and AD204 provide total galvanic isolation between the input and output stages of the isolation amplifier through the use of internal transformer-coupling. The functionally complete AD202 and AD204 eliminate the need for an external, user-supplied dc/dc converter. This permits the designer to minimize the necessary circuit overhead and consequently reduce the overall design and component costs.

The design of the AD202 and AD204 emphasizes maximum flexibility and ease of use, including the availability of an uncommitted op amp on the input stage. They feature a bipolar ±5V output range, an adjustable gain range of from 1 to 100V/V, ±0.025% max nonlinearity (K grade), 130dB of CMR and the AD204 consumes a low 35mW of power.

PRODUCT HIGHLIGHTS

The AD202 and AD204 are full-featured isolators offering numerous benefits to the user:

Small Size: The AD202 and AD204 are available in SIP and DIP form packages. The SIP package is just 0.25" wide, giving the user a channel density of four channels per inch. The isolation barrier is positioned to maximize input to output spacing. For applications requiring a low profile, the DIP package provides a height of just 0.350".

High Accuracy: With a maximum nonlinearity of ±0.025% for the AD202K/AD204K (±0.05% for the AD202J/AD204J) and low drift over temperature, the AD202 and AD204 provide high isolation without loss of signal integrity.

Low Power: Power consumption of 35mW (AD204) and 75mW (AD202) over the full signal range makes these isolators ideal for use in applications with large channel counts or tight power budgets.

Wide Bandwidth: The AD204's full-power bandwidth of 5kHz makes it useful for wideband signals. It is also effective in applications like control loops, where limited bandwidth could result in instability.

Excellent Common-Mode Performance: The AD202K/AD204K provide ±2000V pk continuous common-mode isolation, while the AD202J/AD204J provide ±1000V pk continuous common-mode isolation. All models have a total common-mode input capacitance of less than 5pF inclusive of power isolation. This results in CMR ranging from 130dB at a gain of 100 to 104dB (minimum at unity gain) and very low leakage current (2μA maximum).

Flexible Input: An uncommitted op amp is provided at the input of all models. This provides buffering and gain as required, and facilitates many alternative input functions including filtering, summing, high-voltage ranges, and current (transimpedance) input.

Isolated Power: The AD204 can supply isolated power of ±7.5V at 2mA. This is sufficient to operate a low-drift input preamp, provide excitation to a semiconductor strain gage, or to power any of a wide range of user-supplied ancillary circuits. The AD202 can supply ±7.5V at 0.4mA which is sufficient to operate adjustment networks or low-power references and op amps, or to provide an open-input alarm.

DIFFERENCES BETWEEN THE AD202 AND AD204

The primary distinction between the AD202 and AD204 is in the method by which they are powered: the AD202 operates directly from +15V dc while the AD204 is powered by a non-isolated externally-supplied clock (AD246) which can drive up to 32 AD204s. The main advantages of using the externally-clocked AD204 over the AD202 are reduced cost in multichannel applications, lower power consumption, and higher bandwidth. In addition, the AD204 can supply substantially more isolated power than the AD202.

Of course, in a great many situations, especially where only one or a few isolators are used, the convenience of stand-alone operation provided by the AD202 will be more significant than any of the AD204's advantages. There may also be cases where it is desirable to accommodate either device interchangeably, so the pinouts of the two products have been designed to make that easy to do.

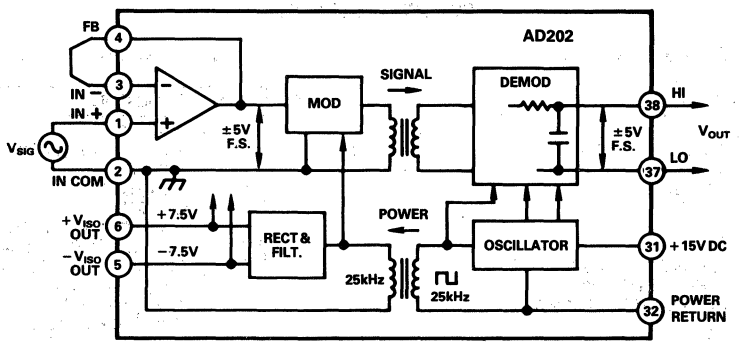

Figure 1a. AD202 Functional Block Diagram

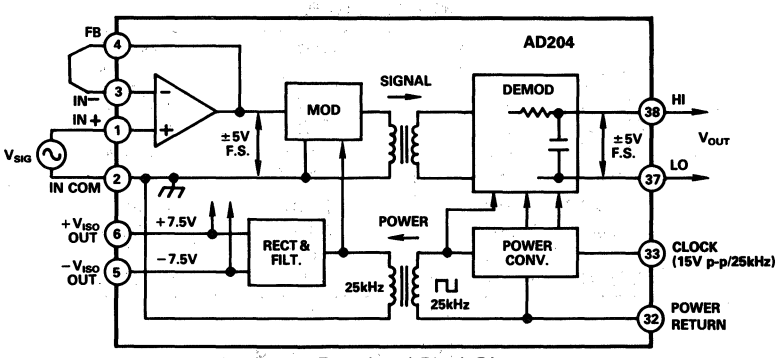

Figure 1b. AD204 Functional Block Diagram
(Pin Designations Apply to the DIP-Style Package.)

INSIDE THE AD202 AND AD204

The AD202 and AD204 use an amplitude modulation technique to permit transformer coupling of signals down to dc (Figure 1a and 1b). Both models also contain an uncommitted input op amp and a power transformer which provides isolated power to the op amp, the modulator, and any external load. The power transformer primary is driven by a 25kHz, 15V p-p square wave which is generated internally in the case of the AD202, or supplied externally for the AD204.

Within the signal swing limits of approximately ±5V, the output voltage of the isolator is equal to the output voltage of the op amp; that is, the isolation barrier has unity gain. The output signal is not internally buffered, so the user is free to interchange the output leads to get signal inversion. Additionally, in multichannel applications, the unbuffered outputs can be multiplexed with one buffer following the mux. This technique minimizes offset errors while reducing power consumption and cost. The output resistance of the isolator is typically 3kΩ for the AD204 (7kΩ for AD202) and varies with signal level and temperature, so it should not be loaded (see Figure 2 for the effects of load upon nonlinearity and gain drift). In many cases a high-impedance load will be present or a following circuit such as an output filter can serve as a buffer, so that a separate buffer function will not often be needed.

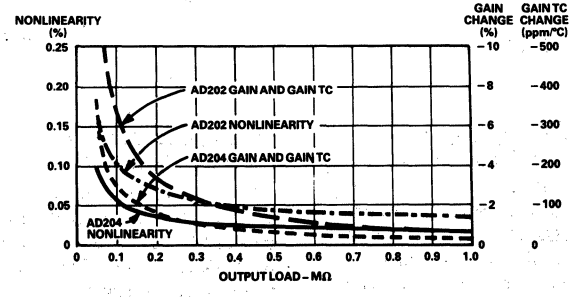

Figure 2. Effects of Output Loading

(Circuit figures shown on this page are for SIP style packages. Refer to page 3 for proper DIP package pin-out.)

USING THE AD202 AND AD204

Powering the AD202. The AD202 requires only a single +15V power supply connected as shown in Figure 3a. A bypass capacitor is provided in the module.

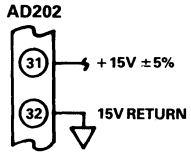

Figure 3a.

Powering the AD204. The AD204 gets its power from an externally supplied clock signal (a 15V p-p square wave with a nominal frequency of 25kHz) as shown in Figure 3b.

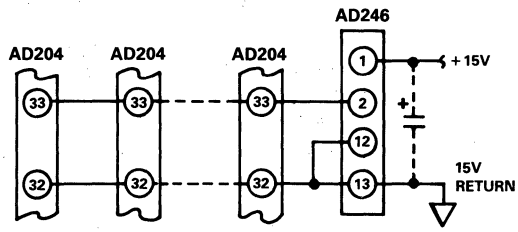

Figure 3b.

AD246 Clock Driver. The AD246 is a compact, inexpensive clock driver that can be used to obtain the required clock from a single 15V supply. Alternatively, the circuit shown in Figure 4 (essentially an AD246) can be used. In either case, one clock circuit can operate at least 32 AD204s at the rated minimum supply voltage of 14.25V and one additional isolator can be operated for each 40mV increase in supply voltage up to 15V. A supply bypass capacitor is included in the AD246, but if many AD204s are operated from a single AD246, an external bypass capacitor should be used with a value of at least 1μF for every five isolators used. Place the capacitor as close as possible to the clock driver.

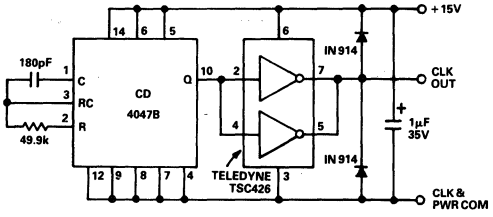

Figure 4. Clock Driver

(Circuit figures shown on this page are for SIP style packages. Refer to page 3 for proper DIP package pin-out.)

Input Configurations. The AD202 and AD204 have been designed to be very easy to use in a wide range of applications. The basic connection for standard unity gain applications, useful for signals up to ±5V, is shown in Figure 5; some of the possible variations are described below. When smaller signals must be

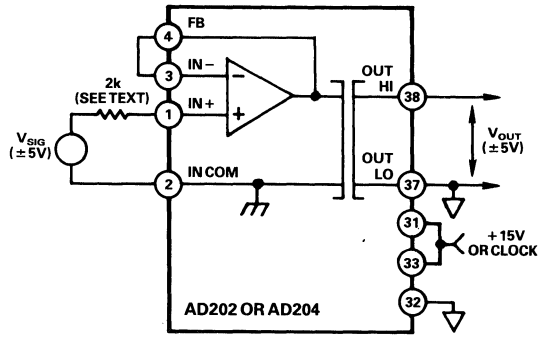

Figure 5. Basic Unity-Gain Application

handled, Figure 6 shows how to get gain while preserving a very high input resistance. The value of feedback resistor R_F should be kept above 20kΩ for best results. Whenever a gain of more than five is taken, a 100pF capacitor from FB to IN COM is required. At lower gains this capacitor is unnecessary, but it will not adversely affect performance if used.

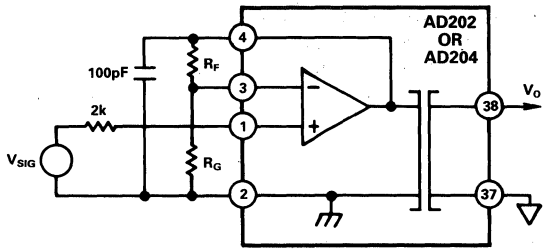

Figure 6. Input Connections for Gain > 1

The "noninverting" circuit of Figures 5 and 6 can also be used to advantage when a signal inversion is needed: just interchange either the input leads or the output leads to get inversion. This approach retains the high input resistance of the "noninverting" circuit, and at unity gain no gain-setting resistors are needed.

When the isolator is not powered, a negative input voltage of more than about 2V will cause an input current to flow. If the signal source can supply more than a few mA under such conditions, the 2kΩ resistor shown in series with IN+ should be used to limit current to a safe value. This is particularly important with the AD202, which may not start if a large input current is present.

Figure 7 shows how to accommodate current inputs or sum currents or voltages. This circuit can also be used when the input signal is larger than the ±5V input range of the isolator; for example, a ±50V input span can be accommodated with R_F = 20k and R_S = 200k. Once again, a capacitor from FB to IN COM is required for gains above 5.

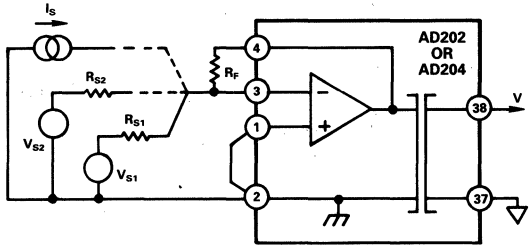

Figure 7. Connections for Summing or Current Inputs

Adjustments. When gain and zero adjustments are needed, the circuit details will depend on whether adjustments are to be made at the isolator input or output, and (for input adjustments) on the input circuit used. Adjustments are usually best done on the input side, because it is better to null the zero ahead of the gain, and because gain adjustment is most easily done as part of the gain-setting network. Input adjustments are also to be preferred when the pots will be near the input end of the isolator (to minimize common-mode strays). Adjustments on the output side might be used if pots on the input side would represent a hazard due to the presence of large common-mode voltages during adjustment.

Figure 8a shows the input-side adjustment connections for use with the "noninverting" connection of the input amplifier. The zero adjustment circuit injects a small adjustment voltage in series with the low side of the signal source. (This will not work if the source has another current path to input common or if current flows in the signal source LO lead). Since the adjustment voltage is injected ahead of the gain, the values shown will work for any gain. Keep the resistance in series with input LO below a few hundred ohms to avoid CMR degradation.

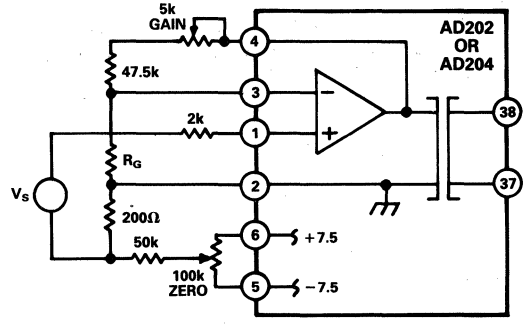

Figure 8a. Adjustments for Noninverting Connection of Op Amp

Also shown in Figure 8a is the preferred means of adjusting the gain-setting network. The circuit shown gives a nominal R_F of 50kΩ, and will work properly for gains of ten or greater. The adjustment becomes less effective at lower gains (its effect is halved at G = 2) so that the pot will have to be a larger fraction of the total R_F at low gain. At G = 1 (follower) the gain cannot be adjusted downward without compromising input resistance; it is better to adjust gain at the signal source or after the output.

Figure 8b shows adjustments for use with inverting input circuits. The zero adjustment nulls the voltage at the summing node. This method is preferable to current injection because it is less affected by subsequent gain adjustment. Gain adjustment is again done in the feedback; but in this case it will work all the way down to unity gain (and below) without alteration.

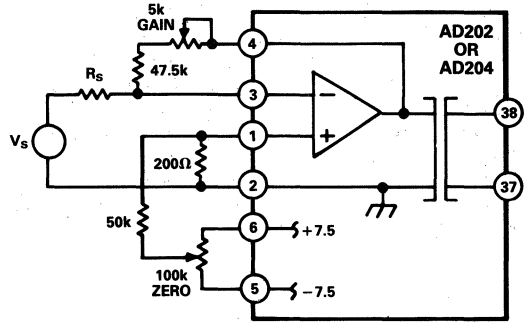

Figure 8b. Adjustments for Summing or Current Input

(Circuit figures shown on this page are for SIP style packages. Refer to page 3 for proper DIP package pin-out.)

Figure 9 shows how zero adjustment is done at the output by taking advantage of the semi-floating output port. The range of this adjustment will have to be increased at higher gains; if that is done, be sure to use a suitably stable supply voltage for the pot circuit.

There is no easy way to adjust gain at the output side of the isolator itself. If gain adjustment must be done on the output side, it will have to be in a following circuit such as an output buffer or filter.

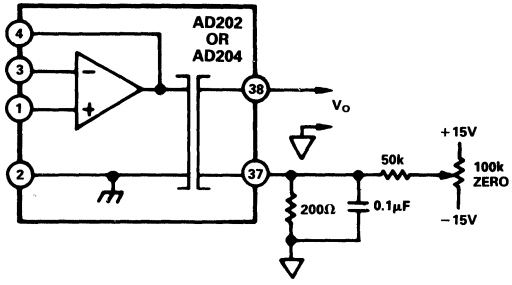

Figure 9. Output-Side Zero Adjustment

Common-Mode Performance. Figures 10a and 10b show how the common-mode rejection of the AD202 and AD204 varies with frequency, gain, and source resistance. For these isolators, the significant resistance will normally be that the path from the source of the common-mode signal to IN COM. The AD202 and AD204 also perform well in applications requiring rejection of fast common-mode steps, as described in the Applications section.

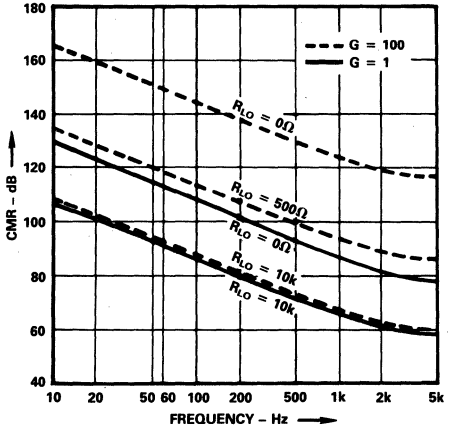

Figure 10a. AD204

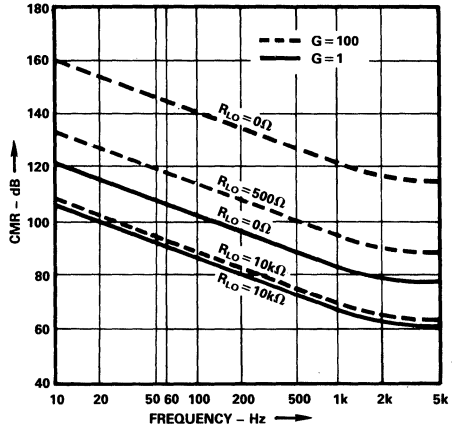

Figure 10b. AD202

APPLICATION EXAMPLE

Process Current Input with Offset. Figure 11 shows an isolator receiver which translates a 4-20mA process current signal into a 0 to +10V output. A 1V to 5V signal appears at the isolator's output, and a −1V reference applied to output LO provides the necessary level shift (in multichannel applications, the reference can be shared by all channels). This technique is often useful for getting offset with a follower-type output buffer.

The circuit as shown requires a source compliance of at least 5V, but if necessary that can be reduced by using a lower value of current-sampling resistor and configuring the input amplifier for a small gain.

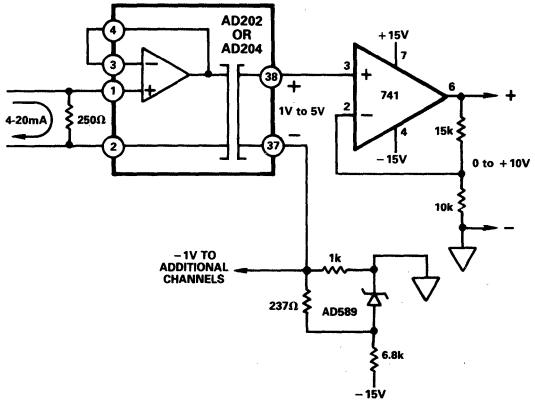

Figure 11. Process Current Input Isolator with Offset

(Circuit figures shown on this page are for SIP style packages. Refer to page 3 for proper DIP package pin-out.)

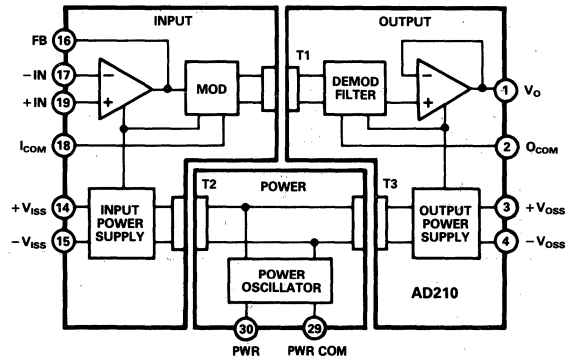
±3500V Peak Continuous
Small Size: 1.00″ × 2.10″ × 0.350″
Three-Port Isolation: Input, Output, and Power
Low Nonlinearity: ±0.012% max
Wide Bandwidth: 20kHz Full-Power (−3dB)
Low Gain Drift: ±25ppm/°C max
High CMR: 120dB (G = 100V/V)
Isolated Power: ±15V @ ±5mA
Uncommitted Input Amplifier

APPLICATIONS

Multichannel Data Acquisition
High Voltage Instrumentation Amplifier
Current Shunt Measurements
Process Signal Isolation

FUNCTIONAL BLOCK DIAGRAM



GENERAL DESCRIPTION

The AD210 is the latest member of a new generation of low cost, high performance isolation amplifiers. This three-port, wide bandwidth isolation amplifier is manufactured with surface-mounted components in an automated assembly process. The AD210 combines design expertise with state-of-the-art manufacturing technology to produce an extremely compact and economical isolator whose performance and abundant user features far exceed those offered in more expensive devices.

The AD210 provides a complete isolation function with both signal and power isolation supplied via transformer coupling internal to the module. The AD210's functionally complete design, powered by a single +15V supply, eliminates the need for an external DC/DC converter, unlike optically coupled isolation devices. The true three-port design structure permits the AD210 to be applied as an input or output isolator, in single or multichannel applications. The AD210 will maintain its high performance under sustained common-mode stress.

Providing high accuracy and complete galvanic isolation, the AD210 interrupts ground loops and leakage paths, and rejects common-mode voltage and noise that may otherwise degrade measurement accuracy. In addition, the AD210 provides protection from fault conditions that may cause damage to other sections of a measurement system.

PRODUCT HIGHLIGHTS

The AD210 is a full-featured isolator providing numerous user benefits including:

High Common-Mode Performance: The AD210 provides 2500V rms (Continuous) and ±3500V peak (Continuous) common-mode voltage isolation between any two ports. Low input to output capacitance of 5pF results in a 120dB CMR at a gain of 100, and a low leakage current (2μA rms max @ 240V rms, 60Hz).

High Accuracy: With maximum nonlinearity of ±0.012% (B Grade), gain drift of ±25ppm/°C max, and input offset drift of (±10 ± 30/G) μV/°C, the AD210 assures signal integrity while providing high level isolation.

Wide Bandwidth: The AD210's full-power bandwidth of 20kHz makes it useful for wideband signals. It is also effective in applications like control loops, where limited bandwidth could result in instability.

Small Size: The AD210 provides a complete isolation function in a small DIP package just 1.00″ × 2.10″ × 0.350″. The low profile DIP package allows application in 0.5″ card racks and assemblies. The pinout is optimized to facilitate board layout while maintaining isolation spacing between ports.

Three-Port Design: The AD210's three-port design structure allows each port (Input, Output, and Power) to remain independent. This three-port design permits the AD210 to be used as an input or output isolator. It also provides additional system protection should a fault occur in the power source.

Isolated Power: ±15V @ 5mA is available at the input and output sections of the isolator. This feature permits the AD210 to excite floating signal conditioners, front-end amplifiers and remote transducers at the input as well as other circuitry at the output.

Flexible Input: An uncommitted operational amplifier is provided at the input. This amplifier provides buffering and gain as required, and facilitates many alternative input functions as required by the user.

CAUTION
ESD (electrostatic discharge) sensitive device. Permanent damage may occur on unconnected devices subject to high energy electrostatic fields. Unused devices must be stored in conductive foam or shunts. The protective foam should be discharged to the destination socket before devices are removed.

INSIDE THE AD210

The AD210 basic block diagram is illustrated in Figure 1. A +15V supply is connected to the power port, and ±15V isolated power is supplied to both the input and output ports via a 50kHz carrier frequency. The uncommitted input amplifier can be used to supply gain or buffering of input signals to the AD210. The fullwave modulator translates the signal to the carrier frequency for application to transformer T1. The synchronous demodulator in the output port reconstructs the input signal. A 20kHz, three-pole filter is employed to minimize output noise and ripple. Finally, an output buffer provides a low impedance output capable of driving a 2kΩ load.

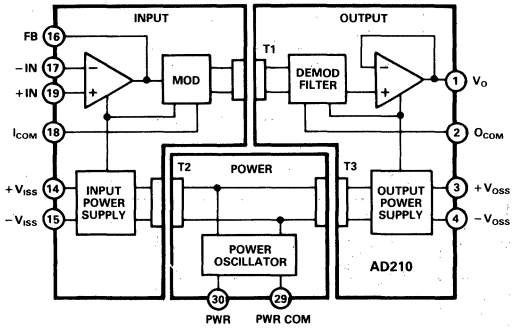

Figure 1. AD210 Block Diagram

USING THE AD210

The AD210 is very simple to apply in a wide range of applications. Powered by a single +15V power supply, the AD210 will provide outstanding performance when used as an input or output isolator, in single and multichannel configurations.

Input Configurations: The basic unity gain configuration for signals up to ±10V is shown in Figure 2. Additional input amplifier variations are shown in the following figures. For smaller signal levels Figure 3 shows how to obtain gain while maintaining a very high input impedance.

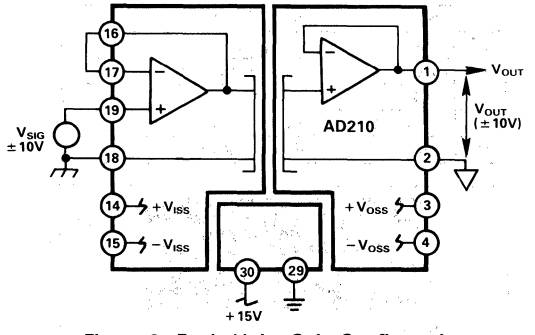

Figure 2. Basic Unity Gain Configuration

The high input impedance of the circuits in Figures 2 and 3 can be maintained in an inverting application. Since the AD210 is a three-port isolator, either the input leads or the output leads may be interchanged to create the signal inversion.

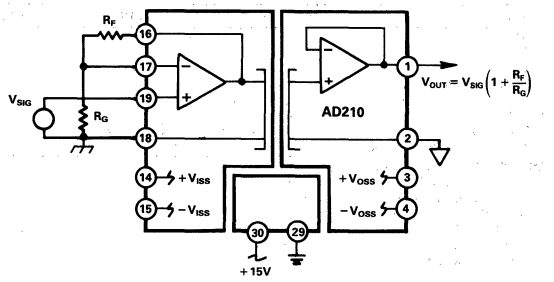

Figure 3. Input Configuration for G>1

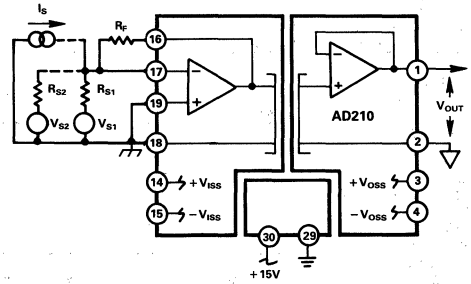
Figure 4 shows how to accommodate current inputs or sum currents or voltages. This circuit configuration can also be used for signals greater than ±10V. For example, a ±100V input span can be handled with $R_F = 20k\Omega$ and $R_{S1} = 200k\Omega$.



$$V_{OUT} = -R_F\left(\frac{V_{S1}}{R_{S1}} + \frac{V_{S2}}{R_{S2}} + I_S + \ldots\right)$$

Figure 4. Summing or Current Input Configuration

Adjustments

When gain and offset adjustments are required, the actual circuit adjustment components will depend on the choice of input configuration and whether the adjustments are to be made at the isolator's input or output. Adjustments on the output side might be used when potentiometers on the input side would represent a hazard due to the presence of high common-mode voltage during adjustment. Offset adjustments are best done at the input side, as it is better to null the offset ahead of the gain.

Figure 5 shows the input adjustment circuit for use when the input amplifier is configured in the noninverting mode. This offset adjustment circuit injects a small voltage in series with the

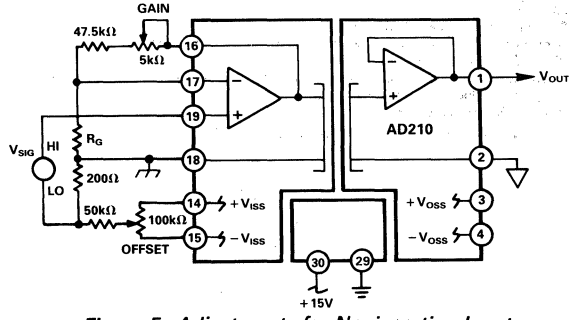


Figure 5. Adjustments for Noninverting Input

low side of the signal source. This will not work if the source has another current path to input common or if current flows in the signal source LO lead. To minimize CMR degradation, keep the resistor in series with the input LO below a few hundred ohms.

Figure 5 also shows the preferred gain adjustment circuit. The circuit shows R_F of 50kΩ, and will work for gains of ten or greater. The adjustment becomes less effective at lower gains (its effect is halved at G=2) so that the pot will have to be a larger fraction of the total R_F at low gain. At G=1 (follower) the gain cannot be adjusted downward without compromising input impedance; it is better to adjust gain at the signal source or after the output.

Figure 6 shows the input adjustment circuit for use when the input amplifier is configured in the inverting mode. The offset adjustment nulls the voltage at the summing node. This is preferable to current injection because it is less affected by subsequent gain adjustment. Gain adjustment is made in the feedback and will work for gains from 1 to 100V/V.

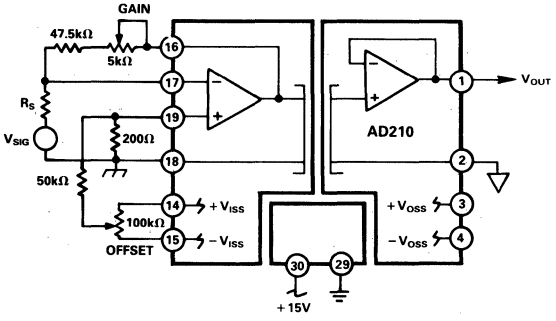

Figure 6. Adjustments for Inverting Input

Figure 7 shows how offset adjustments can be made at the output, by offsetting the floating output port. In this circuit, ±15V would be supplied by a separate source. The AD210's output amplifier is fixed at unity, therefore, output gain must be made in a subsequent stage.

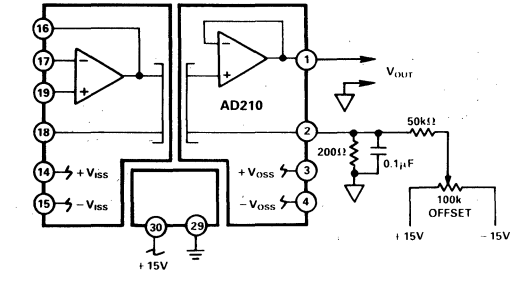

Figure 7. Output-Side Offset Adjustment

PERFORMANCE CHARACTERISTICS

Common-Mode Rejection: Figure 9 shows the common-mode rejection of the AD210 versus frequency, gain and input source resistance. For maximum common-mode rejection of unwanted signals, keep the input source resistance low and carefully lay out the input, avoiding excessive stray capacitance at the input terminals.

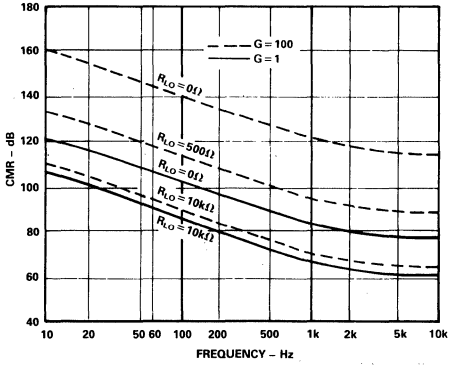

Figure 9. Common-Mode Rejection vs. Frequency

Phase Shift: Figure 10 illustrates the AD210's low phase shift and gain versus frequency. The AD210's phase shift and wide bandwidth performance make it well suited for applications like power monitors and controls systems.

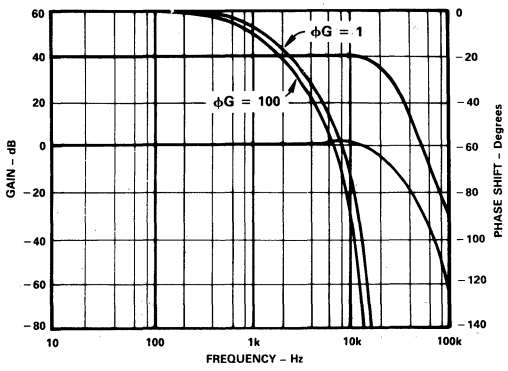

Figure 10. Phase Shift and Gain vs. Frequency

Isolated Power: The AD210 provides isolated power at the input and output ports. This power is useful for various signal conditioning tasks. Both ports are rated at a nominal ±15V at 5mA.

The load characteristics of the isolated power supplies are shown in Figure 15. For example, when measuring the load rejection of the input isolated supplies V_{ISS}, the load is placed between $+V_{ISS}$ and $-V_{ISS}$. The curves labeled V_{ISS} and V_{OSS} are the individual load rejection characteristics of the input and the output supplies, respectively.

There is also some effect on either isolated supply when loading the other supply. The curve labeled CROSSLOAD indicates the sensitivity of either the input or output supplies as a function of the load on the opposite supply.

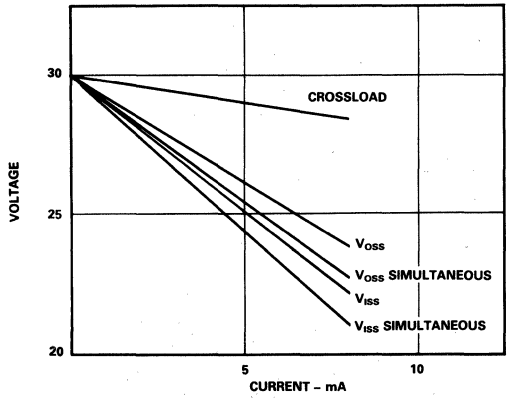

Figure 15. Isolated Power Supplies vs. Load

Lastly, the curves labeled V_{OSS} simultaneous and V_{ISS} simultaneous indicate the load characteristics of the isolated power supplies when an equal load is placed on both supplies.

The AD210 provides short circuit protection for its isolated power supplies. When either the input supplies or the output supplies are shorted to input common or output common, respectively, no damage will be incurred, even under continuous application of the short. However, the AD210 may be damaged if the input and output supplies are shorted simultaneously.

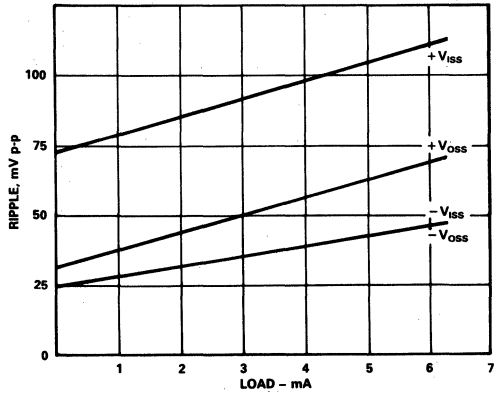

Figure 16a. Isolated Supply Ripple vs. Load (External 4.7μF Bypass)

Under any circumstances, care should be taken to ensure that the power supplies do not accidentally become shorted.

The isolated power supplies exhibit some ripple which varies as a function of load. Figure 16a shows this relationship. The AD210 has internal bypass capacitance to reduce the ripple to a point where performance is not affected, even under full load. Since the internal circuitry is more sensitive to noise on the negative supplies, these supplies have been filtered more heavily. Should a specific application require more bypassing on the isolated power supplies, there is no problem with adding external capacitors. Figure 16b depicts supply ripple as a function of external bypass capacitance under full load.

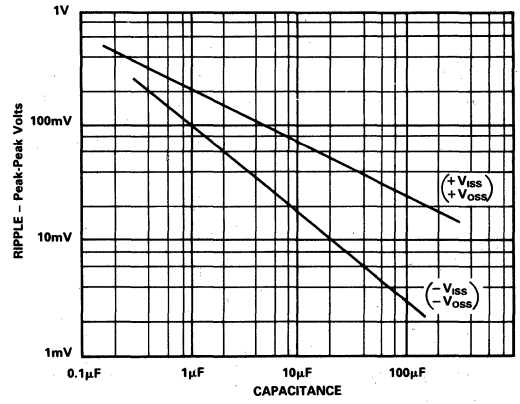

Figure 16b. Isolated Power Supply Ripple vs. Bypass Capacitance (Volts p-p, 1MHz Bandwidth, 5mA Load)

Isolated V-to-I Converter

Illustrated in Figure 19, the AD210 is used to convert a 0 to +10V input signal to an isolated 4-20mA output current. The AD210 isolates the 0 to +10V input signal and provides a proportional voltage at the isolator's output. The output circuit converts the input voltage to a 4-20mA output current, which in turn is applied to the loop load R_{LOAD}.

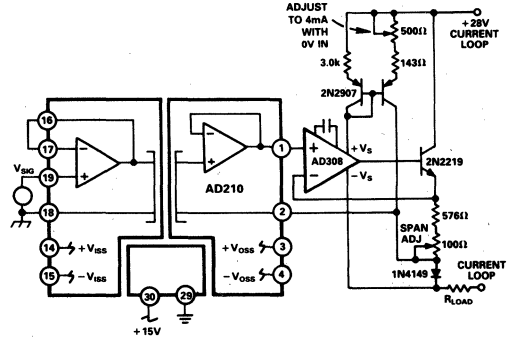

Figure 19. Isolated Voltage-to-Current Loop Converter

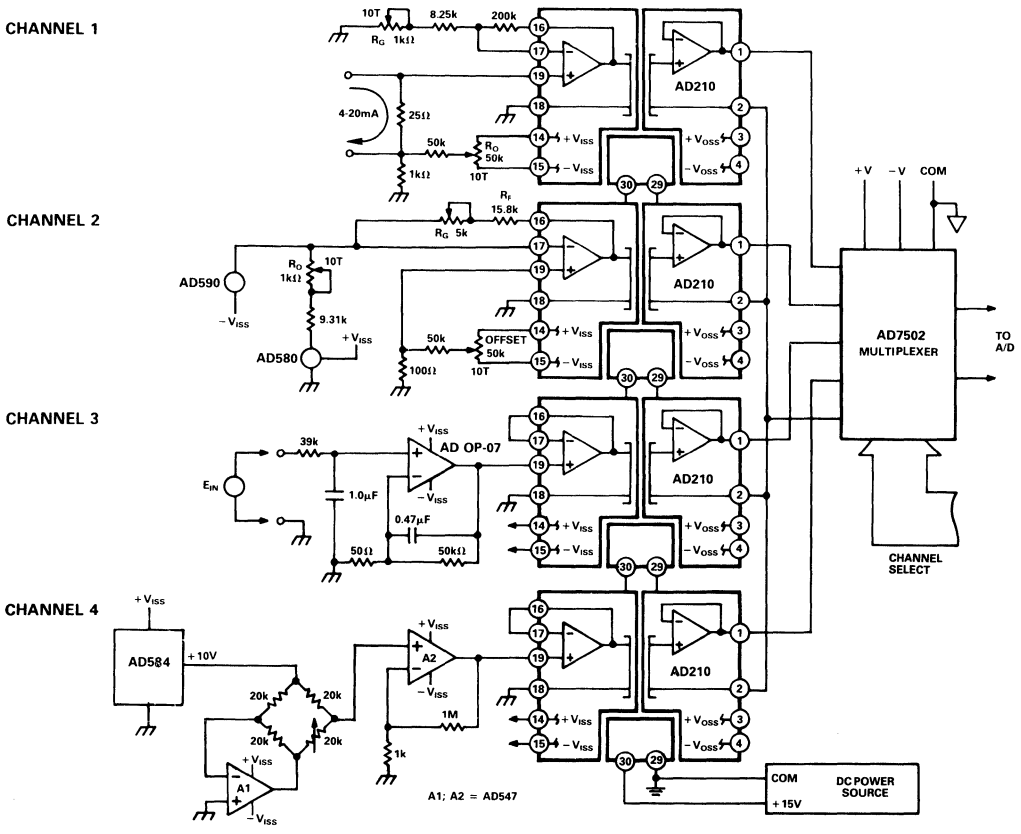

Figure 22. Multichannel Data Acquisition Front End

MULTICHANNEL DATA ACQUISITION FRONT-END

Illustrated in Figure 22 is a four-channel data acquisition front-end used to condition and isolate several common input signals found in various process applications. In this application, each AD210 will provide complete isolation from input to output as well as channel to channel. By using an isolator per channel, maximum protection and rejection of unwanted signals is obtained. The three-port design allows the AD210 to be configured as an input or output isolator. In this application the isolators are configured as input devices with the power port providing additional protection from possible power source faults.

Channel 1: The AD210 is used to convert a 4-20mA current loop input signal into a 0-10V input. The 25Ω shunt resistor converts the 4-20mA current into a +100 to +500mV signal. The signal is offset by −100mV via R_O to produce a 0 to +400mV input. This signal is amplified by a gain of 25 to produce the desired 0 to +10V output. With an open circuit, the AD210 will show −2.5V at the output.

Channel 2: In this channel, the AD210 is used to condition and isolate a current output temperature transducer, Model AD590. At +25°C, the AD590 produces a nominal current of 298.2μA. This level of current will change at a rate of 1μA/°C. At −17.8°C (0°F), The AD590 current will be reduced by 42.8μA to +255.4μA. The AD580 reference circuit provides an equal but opposite current, resulting in a zero net current flow, producing a 0V output from the AD210. At +100°C (+212°F), the AD590 current output will be 373.2μA minus the 255.4μA offsetting current from the AD580 circuit to yield a +117.8μA input current. This current is converted to a voltage via R_F and R_G to produce an output of +2.12V. Channel 2 will produce an output of +10mV/°F over a 0 to +212°F span.

Channel 3: Channel 3 is a low level input channel configured with a high gain amplifier used to condition millivolt signals. With the AD210's input set to unity and the input amplifier set for a gain of 1000, a ±10mV input will produce a ±10V at the AD210's output.

Channel 4: Channel 4 illustrates one possible configuration for conditioning a bridge circuit. The AD584 produces a +10V excitation voltage, while A1 inverts the voltage, producing negative excitation. A2 provides a gain of 1000V/V to amplify the low level bridge signal. Additional gain can be obtained by reconfiguration of the AD210's input amplifier. $\pm V_{ISS}$ provides the complete power for this circuit, eliminating the need for a separate isolated excitation source.

Each channel is individually addressed by the multiplexer's channel select. Additional filtering or signal conditioning should follow the multiplexer, prior to an analog-to-digital conversion stage.

ANALOG DEVICES

Fast, Precision Comparator

AD790

FEATURES

- 45 ns max Propagation Delay
- Single +5 V or Dual ±15 V Supply Operation
- CMOS or TTL Compatible Output
- 250 μV max Input Offset Voltage
- 500 μV max Input Hysteresis Voltage
- 15 V max Differential Input Voltage
- On-Board Latch
- 60 mW Power Dissipation
- Available in 8-Pin Plastic and Hermetic Cerdip Packages
  - MIL-STD-883B Processing Available
- Available in Tape and Reel in Accordance with EIA-481A Standard

APPLICATIONS

- Zero-Crossing Detectors
- Overvoltage Detectors
- Pulse-Width Modulators
- Precision Rectifiers
- Discrete A/D Converters
- Delta-Sigma Modulator A/Ds

PRODUCT DESCRIPTION

The AD790 is a fast (45 ns), precise voltage comparator, with a number of features that make it exceptionally versatile and easy to use. The AD790 may operate from either a single +5 V supply or a dual ±15 V supply. In the single-supply mode, the AD790's inputs may be referred to ground, a feature not found in other comparators. In the dual-supply mode it has the unique ability of handling a maximum differential voltage of 15 V across its input terminals, easing their interfacing to large amplitude and dynamic signals.

This device is fabricated using Analog Devices' Complementary Bipolar (CB) process – which gives the AD790's combination of fast response time and outstanding input voltage resolution (1 mV max). To preserve its speed and accuracy, the AD790 incorporates a "low glitch" output stage that does not exhibit the large current spikes normally found in TTL or CMOS output stages. Its controlled switching reduces power supply disturbances that can feed back to the input and cause undesired oscillations. The AD790 also has a latching function which makes it suitable for applications requiring synchronous operation.

The AD790 is available in five performance grades. The AD790J and the AD790K are rated over the commercial temperature range of 0 to +70°C. The AD790A and AD790B are rated over the industrial temperature range of −40°C to +85°C. The AD790S is rated over the military temperature range of −55°C to +125°C and is available processed to MIL-STD-883B, Rev. C.

PRODUCT HIGHLIGHTS

1. The AD790's combination of speed, precision, versatility and low cost makes it suitable as a general purpose comparator in analog signal processing and data acquisition systems.
2. Built-in hysteresis and a low-glitch output stage minimize the chance of unwanted oscillations, making the AD790 easier to use than standard open-loop comparators.
3. The hysteresis combined with a wide input voltage range enables the AD790 to respond to both slow, low level (e.g., 10 mV) signals and fast, large amplitude (e.g., 10 V) signals.
4. A wide variety of supply voltages are acceptable for operation of the AD790, ranging from single +5 V to dual +5 V/ −12 V, ±5 V, or +5 V/±15 V supplies.
5. The AD790's power dissipation is the lowest of any comparator in its speed range.
6. The AD790's output swing is symmetric between V_{LOGIC} and ground, thus providing a predictable output under a wide range of input and output conditions.

ANALOG DEVICES

Ultrafast TTL Comparators

AD9696/AD9698

FEATURES
4.5 ns Propagation Delay
200 ps Maximum Propagation Delay Dispersion
Single +5 V or ±5 V Supply Operation
Complementary Matched TTL Outputs

APPLICATIONS
High Speed Line Receivers
Peak Detectors
Window Comparators
High Speed Triggers
Ultrafast Pulse Width Discriminators

GENERAL DESCRIPTION

The AD9696 and AD9698 are ultrafast TTL-compatible voltage comparators able to achieve propagation delays previously possible only in high performance ECL devices. The AD9696 is a single comparator providing 4.5 ns propagation delay, 200 ps maximum delay dispersion and 1.7 ns setup time. The AD9698 is a dual comparator with equally high performance; both devices are ideal for critical timing circuits in such applications as ATE, communications receivers and test instruments.

Both devices allow the use of either a single +5 V supply or ±5 V supplies. The choice of supplies determines the common mode input voltage range available: −2.2 V to +3.7 V for ±5 V operation, +1.4 V to +3.7 V for single +5 V supply operation.

The differential input stage features high precision, with offset voltages which are less than 2 mV and offset currents less than 1 μA. A latch enable input is provided to allow operation in either sample-and-hold or track-and-hold applications.

The AD9696 and AD9698 are both available as commercial temperature range devices operating from ambient temperatures of 0°C to +70°C, and as extended temperature range devices for ambient temperatures from −55°C to +125°C. Both versions are available qualified to MIL-STD-883 class B.

Package options for the AD9696 include a 10-pin TO-100 metal can, an 8-pin ceramic DIP, an 8-pin plastic DIP, and an 8-lead small outline plastic package. The AD9698 is available in a 16-pin ceramic DIP, a 16-lead ceramic gullwing, a 16-pin plastic DIP, and a 16-lead small outline plastic package. Military qualified versions of the AD9696 come in the TO-100 can and ceramic DIP; the dual AD9698 comes in ceramic DIP.

NOTES

[1]Absolute maximum ratings are limiting values, to be applied individually, and beyond which the serviceability of the circuit may be impaired. Functional operability is not necessarily implied. Exposure to absolute maximum rating conditions for an extended period of time may affect device reliability.

[2]Typical thermal impedances:

AD9696 Metal Can	θ_{JA} = 170°C/W	θ_{JC} = 50°C/W
AD9696 Ceramic DIP	θ_{JA} = 110°C/W	θ_{JC} = 20°C/W
AD9696 Plastic DIP	θ_{JA} = 160°C/W	θ_{JC} = 30°C/W
AD9696 Plastic SOIC	θ_{JA} = 180°C/W	θ_{JC} = 30°C/W
AD9698 Ceramic DIP	θ_{JA} = 90°C/W	θ_{JC} = 25°C/W
AD9698 Plastic DIP	θ_{JA} = 100°C/W	θ_{JC} = 20°C/W
AD9698 Plastic SOIC	θ_{JA} = 120°C/W	θ_{JC} = 20°C/W

[3]Suffixes KH and TH apply only to model AD9696; AD9698 not available in metal can.

[4]Load circuit has 420 Ω from $+V_S$ to output; 460 Ω from output to ground.

[5]$R_S \leq 100\ \Omega$.

[6]Propagation delays measured with 100 mV pulse; 10 mV overdrive.

[7]Supply voltages should remain stable within ±5% for normal operation.

[8]Specification applies to both +5 V and ±5 V supply operation.

[9]Specification applies to only ±5 V supply operation.

[10]Measured with nominal values ±5% of $+V_S$ and $-V_S$.

[11]Although fall time is faster than rise time, the complementary outputs cross at midpoint of logic swing because of delay on start of falling edge.

Specifications subject to change without notice.

12

EXPLANATION OF TEST LEVELS

Test Level

I – 100% production tested.

II – 100% production tested at +25°C, and sample tested at specified temperatures.

III – Sample tested only.

IV – Parameter is guaranteed by design and characterization testing.

V – Parameter is a typical value only.

VI – All devices are 100% production tested at +25°C. 100% production tested at temperature extremes for extended temperature devices; sample tested at temperature extremes for commercial/industrial devices.

ORDERING GUIDE

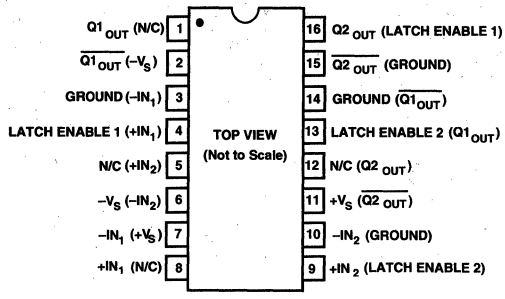
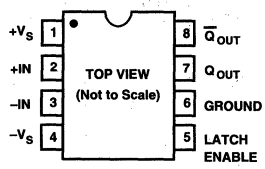
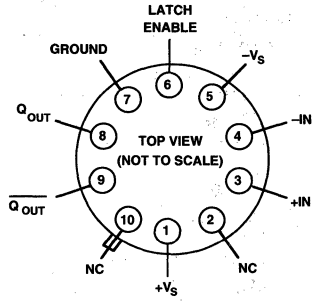
PIN CONFIGURATIONS



AD9698KN/KQ/TQ
[AD9698KR/TZ PINOUTS SHOWN IN ( )]



AD9696KN/KR/KQ/TQ/TZ



AD9696KH/TH

PIN DESCRIPTIONS

Name	Function
$Q1_{OUT}$	One of two complementary outputs. $Q1_{OUT}$ will be at logic HIGH if voltage at $+IN_1$ is greater than voltage at $-IN_1$ and LATCH ENABLE 1 is at logic LOW.
$\overline{Q1_{OUT}}$	One of two complementary outputs. $\overline{Q1_{OUT}}$ will be at logic HIGH if voltage at $-IN_1$ is greater than voltage at $+IN_1$ and LATCH ENABLE 1 is at logic LOW.
GROUND	Analog and digital ground return. All GROUND pins should be connected together and to a low impedance ground plane near the comparator.
LATCH ENABLE 1	Output at $Q1_{OUT}$ will track differential changes at the inputs when LATCH ENABLE 1 is at logic LOW. When LATCH ENABLE 1 is at logic HIGH, the output at $Q1_{OUT}$ will reflect the input state at the application of the latch command, delayed by the Latch Enable Setup Time (t_S). Since the architecture of the input stage (see block diagram) is faster than the logic of the latch stage, data will typically be latched if applied to the comparator(s) within 1.7 ns after the latch. This is the Setup Time (t_S); for guaranteed performance, t_S must be 3 ns.
N/C	No internal connection to comparator.
$-V_S$	Negative power supply connection; nominally −5.2 V.
$-IN_1$	Inverting input of differential input stage for Comparator #1.
$+IN_1$	Noninverting input of differential input stage for Comparator #1.
$+IN_2$	Noninverting input of differential input stage for Comparator #2.
$-IN_2$	Inverting input of differential input stage for Comparator #2.
$+V_S$	Positive power supply connection; nominally +5 V.
LATCH ENABLE 2	Output at $Q2_{OUT}$ will track differential changes at the inputs when LATCH ENABLE 2 is at logic LOW. When LATCH ENABLE 2 is at logic HIGH, the output at $Q2_{OUT}$ will reflect the input state at the application of the latch command, delayed by the Latch Enable Setup Time (t_S). Since the architecture of the input stage (see block diagram) is faster than the logic of the latch stage, data will typically be latched if applied to the comparator(s) within 1.7 ns after the latch. This is the Setup Time (t_S); for guaranteed performance, t_S must be 3 ns.
$\overline{Q2_{OUT}}$	One of two complementary outputs. $\overline{Q2_{OUT}}$ will be at logic HIGH if voltage at $-IN_2$ is greater than voltage at $+IN_2$ and LATCH ENABLE 2 is at logic LOW.
$Q2_{OUT}$	One of two complementary outputs. $Q2_{OUT}$ will be at logic HIGH if voltage at $+IN_2$ is greater than voltage at $-IN_2$ and LATCH ENABLE 2 is at logic LOW.

ANALOG DEVICES

Ultrafast Comparators

AD96685/AD96687

FEATURES
Fast: 2.5ns Propagation Delay
Low Power: 118mW per Comparator
Packages: DIP, TO-100, SOIC, PLCC
Power Supplies: +5V, −5.2V
Logic Compatibility: ECL
MIL-STD-883 Versions Available
50ps Delay Dispersion

APPLICATIONS
High Speed Triggers
High Speed Line Receivers
Threshold Detectors
Window Comparators

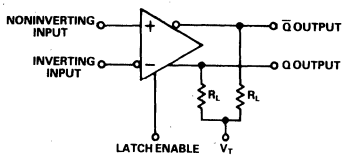
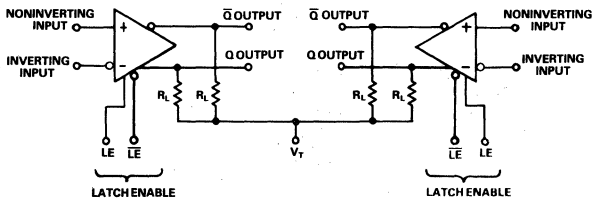
AD96685 FUNCTIONAL BLOCK DIAGRAM



AD96687 FUNCTIONAL BLOCK DIAGRAM



THE OUTPUTS ARE OPEN EMITTERS, REQUIRING EXTERNAL PULL-DOWN RESISTORS. THESE RESISTORS MAY BE IN THE RANGE OF 50Ω – 200Ω CONNECTED TO −2.0V, OR 200Ω – 2000Ω

12

GENERAL DESCRIPTION

The AD96685 and AD96687 are ultrafast voltage comparators. The AD96685 is a single comparator with 2.5ns propagation delay; the AD96687 is an equally fast dual comparator. Both devices feature 50ps propagation delay dispersion which is a particularly important characteristic of high speed comparators. It is a measure of the difference in propagation delay under differing overdrive conditions.

A fast, high precision differential input stage permits consistent propagation delay with a wide variety of signals in the common-mode range from −2.5V to +5V. Outputs are complementary digital signals fully compatible with ECL 10K and 10KH logic families. The outputs provide sufficient drive current to directly drive transmission lines terminated in 50Ω to −2V. A level-sensitive latch input is included which permits tracking, track-hold, or sample-hold modes of operation.

The AD96685 and AD96687 are available in both industrial, −25°C to +85°C, and military temperature ranges. Industrial range devices are available in 16-pin DIP, SOIC, and 20-lead PLCC; additionally, the AD96685 is available in a 10-pin, TO-100 metal can. Both devices are available qualified to MIL-STD-883, Class B in 16-pin ceramic DIP and 20-lead ceramic LCC; the TO-100 version of the AD96685 is also mil-qualified.

ORDERING GUIDE

Device	Type	Temperature Range	Description	Package Options*
AD96685BH	Single	−25°C to +85°C	10-Pin Can, Industrial	H-10A

AD96687TE	Dual	−55°C to +125°C	20-Pin LCC, Extended Temperature	E-20A
AD96687TQ	Dual	−55°C to +125°C	16-Pin DIP, Extended Temperature	Q-16

*For outline information see Package Information section.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

AD96685/AD96687—SPECIFICATIONS

ABSOLUTE MAXIMUM RATINGS[1]

Positive Supply Voltage ($+V_S$) . . . . . +6.5V
Negative Supply Voltage ($-V_S$) . . . . . −6.5V
Input Voltage Range[2] . . . . . ±5V
Differential Input Voltage 5.5V
Latch Enable Voltage . . . . . $-V_S$ to 0V
Output Current 30mA

Operating Temperature Range[3]
AD96685/87/BH/BQ/BP/BR . . . . . −25°C to +85°C
AD96685/87/TE/TH/TQ . . . . . −55°C to +125°C
Storage Temperature Range . . . . . −55°C to +150°C
Junction Temperature . . . . . +175°C
Lead Soldering Temperature (10sec) . . . . . +300°C

ELECTRICAL CHARACTERISTICS (Positive Supply Voltage = +5.0V; Negative Supply Voltage = −5.2V, unless otherwise stated)

NOTES

[1]Absolute maximum ratings are limiting values, to be applied individually, and beyond which serviceability of the circuit may be impaired. Functional operation under any of these conditions is not necessarily implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.

[2]Under no circumstances should the input voltages exceed the supply voltages.

[3]Typical thermal impedances . . .

AD96685 Metal Can	$\theta_{JA} = 172°C/W; \theta_{JC} = 52°C/W$
AD96685 Ceramic	$\theta_{JA} = 115°C/W; \theta_{JC} = 57°C/W$
AD96685 LCC	$\theta_{JA} = 172°C/W; \theta_{JC} = 65°C/W$

[4]$R_S = 100\Omega$.

[5]Input Voltage Range can be extended to −3.3V if $-V_S = -6.0V$.

[6]Outputs terminated through 50Ω to −2.0V.

[7]Propagation delays measured with 100mV pulse (10mV overdrive), to 50% transition point of the output.

[8]Change in propagation Delay from 100mV to 1V input overdrive.

[9]Supply voltages should remain stable within ±5% for normal operation.

[10]Measured at ±5% of $+V_S$ and $-V_S$.

Specifications subject to change without notice.

EXPLANATION OF TEST LEVELS

Test Level

I – 100% production tested.
II – 100% production tested at +25°C, and sample tested at specified temperatures.
III – Sample tested only.
IV – Parameter is guaranteed by design and characterization testing.
V – Parameter is a typical value only.
VI – All devices are 100% production tested at +25°C; 100% production tested at temperature extremes for extended temperature devices; sample tested at temperature extremes for commercial/industrial devices.

FUNCTIONAL DESCRIPTION

Pin Name	Description
$+V_S$	– Positive supply terminal, nominally +5.0V.
NONINVERTING INPUT	– Noninverting analog input of the differential input stage. The NONINVERTING INPUT must be driven in conjunction with the INVERTING INPUT.
INVERTING INPUT	– Inverting analog input of the differential input stage. The INVERTING INPUT must be driven in conjunction with the NONINVERTING INPUT.
LATCH ENABLE	– In the "compare" mode (logic HIGH), the output will track changes at the input of the comparator. In the "latch" mode (logic LOW), the output will reflect the input state just prior to the comparator being placed in the "latch" mode. $\overline{\text{LATCH ENABLE}}$ must be driven in conjunction with LATCH ENABLE for the AD96687.
$\overline{\text{LATCH ENABLE}}$	– In the "compare" mode (logic LOW), the output will track changes at the input of the comparator. In the "latch" mode (logic HIGH), the output will reflect the input state just prior to the comparator being placed in the "latch" mode. LATCH ENABLE must be driven in conjunction with $\overline{\text{LATCH ENABLE}}$ for the AD96687.
$-V_S$	– Negative supply terminal, nominally −5.2V.
Q	– One of two complementary outputs. Q will be at logic HIGH if the analog voltage at the NONINVERTING INPUT is greater than the analog voltage at the INVERTING INPUT (provided the comparator is in the "compare" mode). See LATCH ENABLE and $\overline{\text{LATCH ENABLE}}$ (AD96687 only) for additional information.
$\overline{Q}$	– One of two complementary outputs. $\overline{Q}$ will be at logic LOW if the analog voltage at the NONINVERTING INPUT is greater than the analog voltage at the INVERTING INPUT (provided the comparator is in the "compare" mode). See LATCH ENABLE and $\overline{\text{LATCH ENABLE}}$ (AD96687 only) for additional information.
GROUND 1	– One of two grounds, but primarily associated with the digital ground. Both grounds should be connected together near the comparator.
GROUND 2	– One of two grounds, but primarily associated with the analog ground. Both grounds should be connected together near the comparator.

Quad Low Power, Precision Comparator

CMP04

FEATURES

- **High Gain ..... 200V/mV Typ**
- **Single or Dual Supply Operation**
- **Input Voltage Range Includes Ground**
- **Low Power Consumption (1.5mW/Comparator)**
- **Low Input Bias Current ..... 100nA Max**
- **Low Input Offset Current ..... 10nA Max**
- **Low Offset Voltage ..... 1mV Max**
- **Low Output Saturation Voltage ..... 250mV @ 4mA**
- **Logic Output Compatible with TTL, DTL, ECL, MOS and CMOS**
- **Directly Replaces LM139/239/339 Comparators**
- **Available in Die Form**

† Burn-in is available on commercial and industrial temperature range parts in CerDIP, plastic DIP, and TO-can packages.

GENERAL DESCRIPTION

Four precision independent comparators comprise the CMP-04. Performance highlights include a very low offset voltage, low output saturation voltage and high gain in a single supply design. The input voltage range includes ground for single supply operation and V– for split supplies. A low power supply current of 2mA, which is independent of supply voltage, makes this the preferred comparator for precision applications requiring minimal power consumption. Maximum logic interface flexibility is offered by the open-collector TTL output.

0.5	MAT01GH	MIL

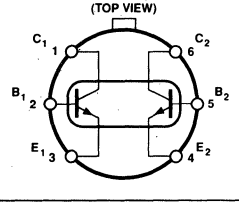
* For devices processed in total compliance to MIL-STD-883, add /883 after part number. Consult factory for 883 data sheet.

† Burn-in is available on commercial and industrial temperature range parts in CerDIP, plastic DIP, and TO-can packages.

GENERAL DESCRIPTION

The MAT-01 is a monolithic dual NPN transistor. An exclusive Silicon Nitride "Triple-Passivation" process provides excellent stability of critical parameters over both temperature and time. Matching characteristics include offset voltage of 40μV, temperature drift of 0.15μV/° C, and h_{FE} matching of 0.7%. Very high h_{FE} is provided over a six decade range of collector current, including an exceptional h_{FE} of 590 at a collector current of only 10nA. The high gain at low collector current makes the MAT-01 ideal for use in low-power, low-level input stages.

PIN CONNECTIONS



TO-78
(H-Suffix)

NOTE:
Substrate is connected to case.

ABSOLUTE MAXIMUM RATINGS (Note 4)

Collector-Base Voltage (BV_{CBO})
MAT-01AH, GH, N 45V
Collector-Emitter Voltage (BV_{CEO})
MAT-01AH, GH, N 45V
Collector-Collector Voltage (BV_{CC})
MAT-01AH, GH, N 45V
Emitter-Emitter Voltage (BV_{EE})
MAT-01AH, GH, N 45V
Emitter-Base Voltage (BV_{EBO}) (Note 1) 5V
Collector Current (I_C) 25mA
Emitter Current (I_E) 25mA
Total Power Dissipation
Case Temperature ≤ 40° C (Note 2) 1.8W
Ambient Temperature ≤ 70° C (Note 3) 500mW
Operating Ambient Temperature ..... −55° C to +125° C
Operating Junction Temperature ..... −55° C to +150° C
Storage Temperature ..... −65° C to +150° C
Lead Temperature (Soldering, 60 sec) ..... 300° C
DICE Junction Temperature ..... −65° C to +150° C

NOTES:
1. Application of reverse bias voltages in excess of rating shown can result in degradation of h_{FE} and h_{FE} matching characteristics. Do not attempt to measure BV_{EBO} greater than the 5V rating shown.
2. Rating applies to applications using heat sinking to control case temperature. Derate linearly at 16.4mW/° C for case temperatures above 40° C.
3. Rating applies to applications not using heat sinking; device in free air only. Derate linearly at 6.3mW/° C for ambient temperatures above 70° C.
4. Absolute maximum ratings apply to both DICE and packaged devices.

GENERAL DESCRIPTION

The design of the MAT-02 series of NPN dual monolithic transistors is optimized for very low noise, low drift, and low r_{BE}. Precision Monolithics' exclusive Silicon Nitride "Triple-Passivation" process stabilizes the critical device parameters over wide ranges of temperature and elapsed time. Also, the high current gain (h_{FE}) of the MAT-02 is maintained over a wide range of collector current. Exceptional characteristics of the MAT-02 include offset voltage of 50μV max (A/E grades) and 150μV max (B/F grades). Device performance is specified over the full military temperature range as well as at 25° C.

Input protection diodes are provided across the emitter-base junctions to prevent degradation of the device characteristics due to reverse-biased emitter current. The substrate is clamped to the most negative emitter by the parasitic isolation junction created by the protection diodes. This results in complete isolation between the transistors.

The MAT-02 should be used in any application where low noise is a priority. The MAT-02 can be used as an input stage to make an amplifier with noise voltage of less than 1.0nV/√Hz at 100Hz. Other applications, such as log/anti-log circuits, may use the excellent logging conformity of the MAT-02. Typical bulk resistance is only 0.3Ω to 0.4Ω. The MAT-02 electrical characteristics approach those of an ideal transistor when operated over a collector current range of 1μA to 10mA. For applications requiring multiple devices see MAT-04 Quad Matched Transistor data sheet.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

† Burn-in is available on industrial temperature range parts.

GENERAL DESCRIPTION

The MAT-03 dual monolithic PNP transistor offers excellent parametric matching and high frequency performance. Low noise characteristics (1nV/√Hz Max @ 1kHz), high bandwidth (190MHz typical), and low offset voltage (100μV Max), makes the MAT-03 an excellent choice for demanding preamplifier applications. Tight current gain matching (3% Max mismatch) and high current gain (100 Min), over a wide range of collector current, makes the MAT-03 an excellent choice for current mirrors. A low value of bulk resistance (typically 0.3Ω) also makes the MAT-03 an ideal component for applications requiring accurate logarithmic conformance.

Each transistor is individually tested to data sheet specifications. Device performance is guaranteed at 25°C and over the extended industrial and military temperature ranges. To insure the long-term stability of the matching parameters, internal protection diodes across the base-emitter junction clamp any reverse base-emitter junction potential. This prevents a base-emitter breakdown condition which can result in degradation of gain and matching performance due to excessive breakdown current.

* For devices processed in total compliance to MIL-STD-883, add /883 after part number. Consult factory for 883 data sheet.

† Burn-in is available on commercial and industrial temperature range parts in CerDIP, plastic DIP, and TO-can packages.

†† For availability and burn-in information on SO and PLCC packages, contact your local sales office.

GENERAL DESCRIPTION

The MAT-04 is a quad monolithic NPN transistor that offers excellent parametric matching for precision amplifier and non-linear circuit applications. Performance characteristics of the MAT-04 include high gain (400 minimum) over a wide range of collector current, low noise (2.5nV/$\sqrt{\text{Hz}}$ maximum at 100Hz, I_C = 1 mA) and excellent logarithmic conformance. The MAT-04 also features a low offset voltage of 200μV and tight current gain matching, to within 2%. Each transistor of the MAT-04 is individually tested to data sheet specifications. For matching parameters (offset voltage, input offset current, and gain match), each of the dual transistor combinations are verified to meet stated limits. Device performance is guaranteed at 25°C and over the industrial and military temperature ranges.

The long-term stability of matching parameters is guaranteed by the protection diodes across the base-emitter junction of each transistor. These diodes prevent degradation of beta and matching characteristics due to reverse bias base-emitter current.

The superior logarithmic conformance and accurate matching characteristics of the MAT-04 makes it an excellent choice for use in log and antilog circuits. The MAT-04 is an ideal choice in applications where low noise and high gain are required.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

Self-Contained Audio Preamplifier

SSM2017

FEATURES

Excellent Noise Performance: 950 pV/$\sqrt{Hz}$ or 1.5 dB Noise Figure
Ultralow THD: <0.01% @ G = 100 Over the Full Audio Band
Wide Bandwidth: 1 MHz @ G = 100
High Slew Rate: 17 V/μs typ
Unity Gain Stable
True Differential Inputs
Subaudio 1/f Noise Corner
8-Pin Mini-DIP with Only One External Component Required
Very Low Cost
Extended Temperature Range: −40°C to +85°C

APPLICATIONS

Audio Mix Consoles
Intercom/Paging Systems
Two-Way Radio
Sonar
Digital Audio Systems

GENERAL DESCRIPTION

The SSM-2017 is a latest generation audio preamplifier combining SSM preamplifier design expertise with advanced processing. The result is excellent audio performance from a self-contained 8-pin mini-DIP device, requiring only one external gain set resistor or potentiometer. The SSM-2017 is further enhanced by its unity gain stability.

Key specifications include ultralow noise (1.5 dB noise figure) and THD (<0.01% at G = 100), complemented by wide bandwidth and high slew rate.

Applications for this low cost device include microphone preamplifiers and bus summing amplifiers in professional and consumer audio equipment, sonar, and other applications requiring a low noise instrumentation amplifier with high gain capability.

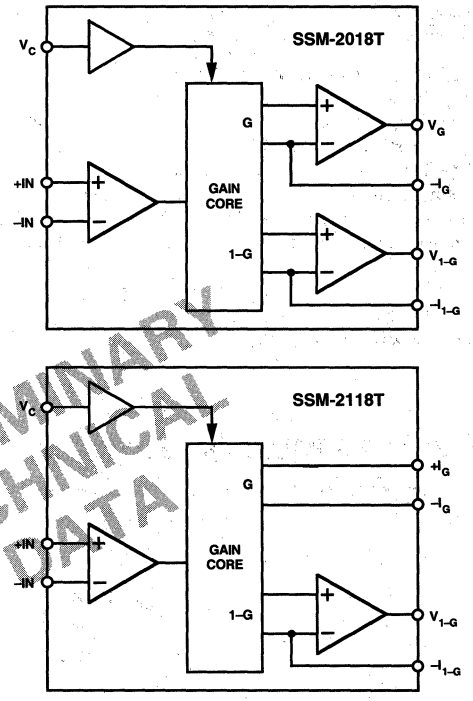
FUNCTIONAL BLOCK DIAGRAMS



GENERAL DESCRIPTION

The SSM2018T and SSM2118T represent continuing evolution of the Frey Operational Voltage Element (OVCE) topology that permits flexibility in the design of high performance volume control systems. Voltage (SSM2018T) and differential current (SSM2118T) output versions are offered, both laser-trimmed for gain core symmetry and offset. As a result, the SSM2018T is the first professional audio quality VCA to offer trimless operation. The SSM2118T is ideal for low noise summing in large VCA based systems.

Due to careful gain core layout, the SSM2018T/SSM2118T combine the low noise of Class AB topologies with the low distortion of Class A circuits to offer an unprecedented level of sonic transparency. Additional features include differential inputs, a 140 dB gain range, and a high impedance control port. The SSM2018T provides an internal current-to-voltage converter; thus no external active components are required. The SSM2118T has fully differential current outputs that permit high noise-immunity summing of multiple channels.

Both devices are offered in 16-pin plastic DIP and SOIC packages and guaranteed for operation over the extended industrial temperature range of –40°C to +85°C.

***Protected by U.S. Patent Nos. 4,471,320 and 4,560,947.**

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the SSM2018T/SSM2118T features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

Quad Current-Controlled Amplifier

SSM2024

FEATURES

- Four VCAs in One Package
- Ground Referenced Current Control Inputs
- 82dB S/N at 0.3 % THD
- Full Class A Operation
- −40dB Control Feedthrough (Untrimmed)
- Easy Signal Summing
- 6% Gain Matching

APPLICATIONS

- Electronic Musical Instruments
- Noise Gating
- Compressor/Limiters
- Signal Mixing
- Automatic Gain Control
- Voltage-Controlled Oscillators

ORDERING INFORMATION

PACKAGE	OPERATING TEMPERATURE RANGE
PLASTIC 16-PIN	
SSM2024P	−10°C to +50°C

GENERAL DESCRIPTION

The SSM-2024 is a quad Class A noninverting current-controlled transconductance amplifier. Each of the four VCAs is completely independent and includes a ground referenced linear current gain control. These voltage-in/current-out amplifiers offer over 82dB S/N at 0.3% THD. Other features include low control voltage feedthrough and minimal external components for most applications. With four matched VCAs in a single IC, the SSM-2024 provides a convenient solution for applications requiring multiple amplifiers. The pinout groups the four outputs for easy signal summing for circuits such as four-channel mixers.

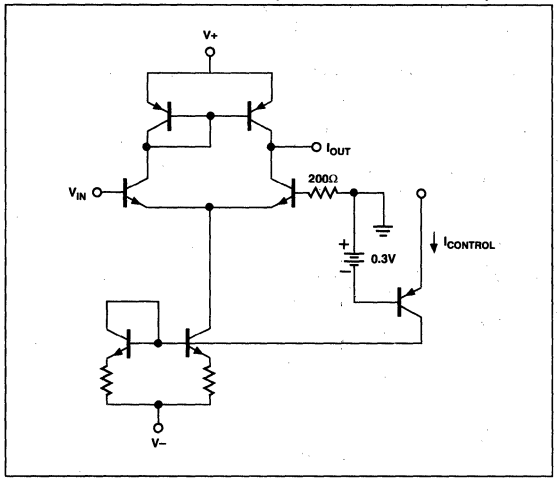
SIMPLIFIED SCHEMATIC (1 OF 4 AMPLIFIERS)



Dual Single-Supply Audio Operational Amplifier

SSM2135

FEATURES

Excellent Sonic Characteristics
High Output Drive Capability
5.2 nV/$\sqrt{Hz}$ Equivalent Input Noise @ 1 kHz
0.001% THD+N (V_O = 2.5 V p-p @ 1 kHz)
3.5 MHz Gain Bandwidth
Unity-Gain Stable
Low Cost

APPLICATIONS

Multimedia Audio Systems
Microphone Preamplifier
Headphone Driver
Differential Line Receiver
Balanced Line Driver
Audio ADC Input Buffer
Audio DAC I-V Converter and Filter
Pseudo-Ground Generator

GENERAL DESCRIPTION

The SSM-2135 Dual Audio Operational Amplifier permits excellent performance in portable or low power audio systems, with an operating supply range of +4 V to +36 V or ±2 V to ±18 V. The unity gain stable device has very low voltage noise of 4.7 nV/$\sqrt{Hz}$, and total harmonic distortion plus noise below 0.01% over normal signal levels and loads. Such characteristics are enhanced by wide output swing and load drive capability. A unique output stage* permits output swing approaching the rail under moderate load conditions. Under severe loading, the SSM-2135 still maintains a wide output swing with ultralow distortion.

Particularly well suited for computer audio systems and portable digital audio units, the SSM-2135 can perform preamplification, headphone and speaker driving, and balanced line driving and receiving. Additionally, the device is ideal for input signal conditioning in single-supply sigma-delta analog-to-digital converter subsystems such as the AD1878/AD1879.

The SSM-2135 is available in 8-pin plastic DIP and SOIC packages, and is guaranteed for operation over the extended industrial temperature range of −40°C to +85°C.

*Protected by U. S. Patent No. 5,146,181.

APPLICATION INFORMATION

The SSM-2135 is a low voltage audio amplifier that has exceptionally low noise and excellent sonic quality even when driving loads as small as 25 Ω. Designed for single supply use, the SSM-2135's inputs common-mode and output swing to zero volts. Thus with a supply voltage at +5 V, both the input and output will swing from 0 V to +4 V. Because of this, signal dynamic range can be optimized if the amplifier is biased to a +2 V reference rather than at half the supply voltage.

The SSM-2135 is unity-gain stable, even when driving into a fair amount of capacitive load. Driving up to 500 pF does not cause any instability in the amplifier. However, overshoot in the frequency response increases slightly.

The SSM-2135 makes an excellent output amplifier for +5 V only audio systems such as a multimedia workstation, a CD output amplifier, or an audio mixing system. The amplifier has large output swing even at this supply voltage because it is designed to swing to the negative rail. In addition, it easily drives load impedances as low as 25 Ω with low distortion.

The SSM-2135 is fully protected from phase reversal for inputs going to the negative supply rail. However, an internal ESD protection diodes will turn "on" when either input is forced more than 0.5 V below the negative rail. Under this condition, input current in excess of 2 mA may cause erratic output behavior, in which case a current limiting resistor should be included in the offending input if phase integrity is required with excessive input voltages. A 500 Ω or higher series input resistor will prevent phase inversion even with the input pulled 1 volt below the negative supply.

"Hot" plugging the input to a signal generally does not present a problem for the SSM-2135, assuming the signal does not have any voltage exceeding the device's supply voltage. If so, it is advisable to add a series input resistor to limit the current, as well as a Zener diode to clamp the input to a voltage no higher than the supply.

APPLICATION CIRCUITS

A Low Noise Stereo Headphone Driver Amplifier

Figure 29 shows the SSM-2135 used in a stereo headphone driver for multimedia applications with the AD1848, a 16-bit stereo codec. The SSM-2135 is equally well suited for the serial-bused AD1849 stereo codec. The headphone's impedance can be as low as 25 Ω, which covers most commercially available high fidelity headphones. Although the amplifier can operate at up to ±18 V supply, it is just as efficient powered by a single +5 V. At this voltage, the amplifier has sufficient output drive to deliver distortion-free sound to a low impedance headphone.

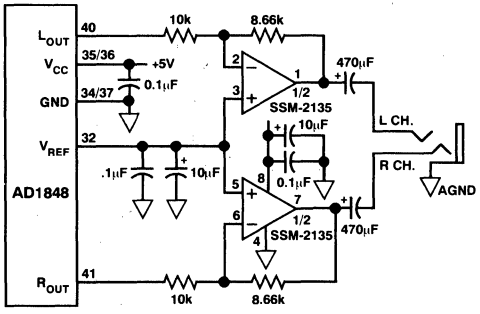

Figure 29. A Stereo Headphone Driver for Multimedia Sound Codec

Figure 30 shows the total harmonic distortion characteristics versus frequency driving into a 32 Ω load, which is a very typical impedance for a high quality stereo headphone. The SSM-2135 has excellent power supply rejection, and as a result, is tolerant of poorly regulated supplies. However, for best sonic quality, the power supply should be well regulated and heavily bypassed to minimize supply modulation under heavy loads. A minimum of 10 μF bypass is recommended.

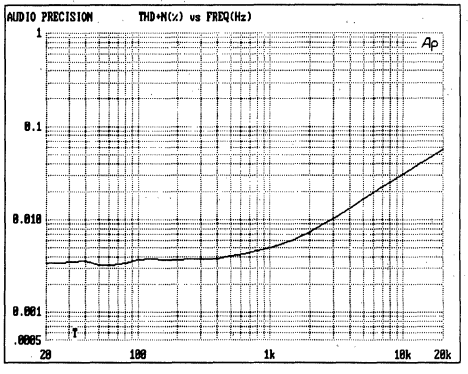

Figure 30. Headphone Driver THD+N vs. Frequency into a 32 Ω Load (V_S = +5 V, with 80 kHz Low-Pass Filter)

A Low Noise Microphone Preamplifier

The SSM-2135's 4.7 nV/√Hz input noise in conjunction with low distortion makes it an ideal device for amplifying low level signals such as those produced by microphones. Figure 31 illustrates a stereo microphone input circuit feeding a multimedia sound codec. As shown, the gain is set at 100 (40 dB), although it can be set to other gains depending on the microphone output levels. Figure 32 shows the preamplifier's harmonic distortion performance with 1 V rms output while operating from a single +5 V supply.

The SSM-2135 is biased to 2.25 V by the V_{REF} pin of the AD1848 codec. The same voltage is buffered by the 2N4124 transistor to provide "phantom power" to the microphone. A typical electret condenser microphone with an impedance range of 100 Ω to 1 kΩ works well with the circuit. This power booster circuit may be omitted for dynamic microphone elements.

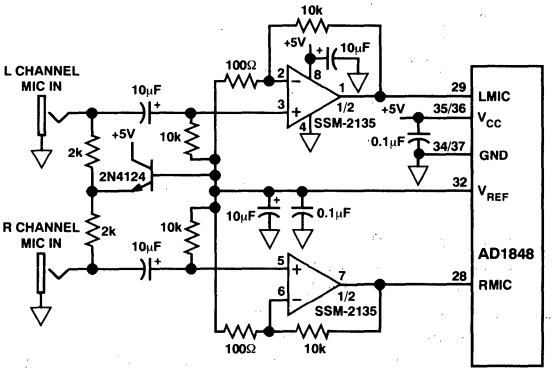

Figure 31. Low Noise Microphone Preamp for Multimedia Sound Codec

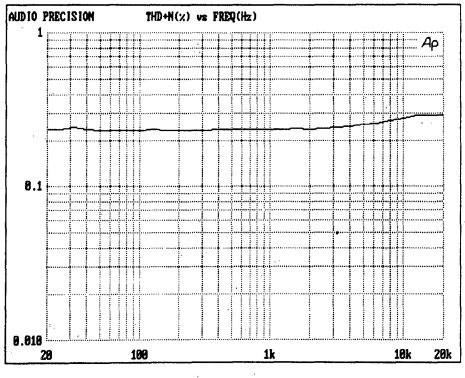

Figure 32. MIC Preamp THD+N Performance (V_S = +5 V, A_V = 40 dB, V_{OUT} = 1 V rms, with 80 kHz Low-Pass Filter)

14

An 18-Bit Stereo CD-DAC Output Amplifier

The SSM-2135 makes an ideal single supply stereo output amplifier for audio D/A converters because of its low noise and distortion. Figure 33 shows the implementation of an 18-Bit stereo DAC channel. The output amplifier also provides low-pass filtering for smoothing the oversampled audio signal. The filter's cutoff frequency is set at 22.5 kHz and it has a maximally flat response from dc to 20 kHz.

As mentioned above, the amplifier's outputs can drive directly into a stereo headphone that has impedance as low as 25 Ω with no additional buffering required.

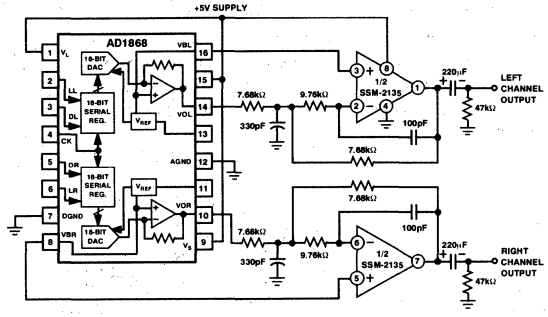

Figure 33. +5 V Stereo 18-Bit DAC

A Single Supply Differential Line Driver

Signal distribution and routing is often required in audio systems, particularly portable digital audio equipment for professional applications. Figure 34 shows a single supply line driver circuit that has differential output. The bottom amplifier provides a 2 V dc bias for the differential amplifier in order to maximize the output swing range. The amplifier can output a maximum of 0.8 V rms signal with a +5 V supply. It is capable of driving into 600 Ω line termination at a reduced output amplitude.

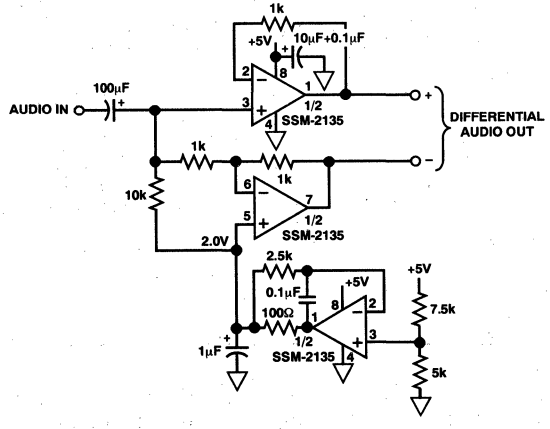

Figure 34. Single Supply Differential Line Driver

A Single Supply Differential Line Receiver

Receiving a differential signal with minimum distortion is achieved using the circuit in Figure 35. Unlike a difference amplifier (a subtractor), the circuit has a true balanced input impedance regardless of input drive levels. That is, each input always presents a 20 kΩ impedance to the source. For best common-mode rejection performance, all resistors around the differential amplifier must be very well matched. Best results can be achieved using a 10 kΩ precision resistor network.

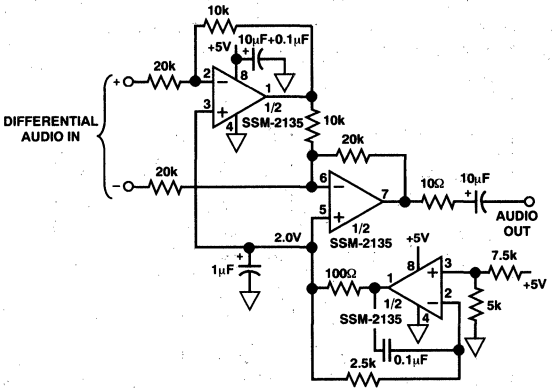

Figure 35. Single Supply Balanced Differential Line Receiver

A Pseudo-Reference Voltage Generator

For single supply circuits, a reference voltage source is often required for biasing purposes or signal offsetting purposes. The circuit in Figure 36 provides a supply splitter function with low output impedance. The 1 μF output capacitor serves as a charge reservoir to handle a sudden surge in demand by the load as well as providing a low ac impedance to it. The 0.1 μF feedback capacitor compensates the amplifier in the presence of a heavy capacitive load, maintaining stability.

The output can source or sink up to 12 mA of current with +5 V supply, limited only by the 100 Ω output resistor. Reducing the resistance will increase the output current capability. Alternatively, increasing the supply voltage to 12 V also improves the output drive to more than 25 mA.

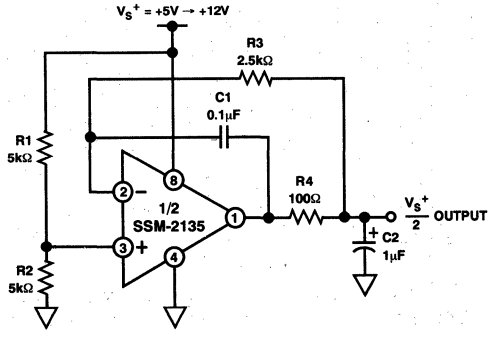

Figure 36. Pseudo-Reference Generator

A Digital Volume Control Circuit

Working in conjunction with the AD7528/PM7528 dual 8-bit D/A converter, the SSM-2135 makes for an efficient audio attenuator, as shown in Figure 37. The circuit works off a single +5 V supply. The DAC's are biased to a 2 V reference level which is sufficient to keep the DAC's internal R-2R ladder switches operating properly. This voltage is also the optimal midpoint of the SSM-2135's common-mode and output swing range. With the circuit as shown, the maximum input and output swing is 1.25 V rms. Total harmonic distortion measures a respectable 0.01% at 1 kHz and 0.1% at 20 kHz. The frequency response at any attenuation level is flat to 20 kHz.

Each DAC can be controlled independently via the 8-bit parallel data bus. The attenuation level is linearly controlled by the binary weighting of the digital data input. Total attenuation ranges from 0 dB to −48 dB.

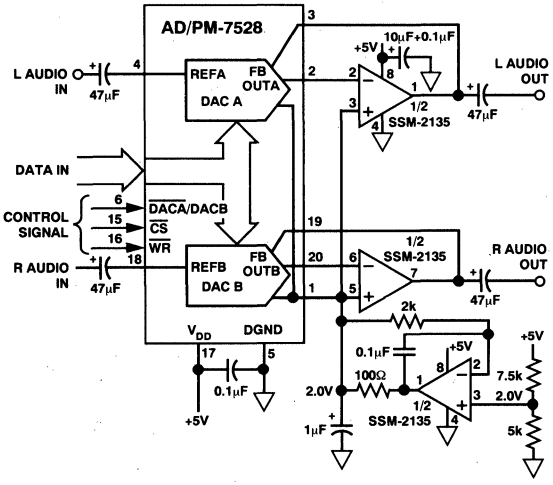

Figure 37. Digital Volume Control

A Logarithmic Volume Control Circuit

Figure 38 shows a logarithmic version of the volume control function. Similar biasing is used. With an 8-bit bus, the AD7111 provides an 88.5 dB attenuation range. Each bit resolves a 0.375 dB attenuation. Refer to AD7111 data sheet for attenuation levels for each input code.

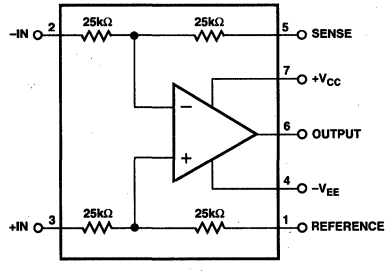
FUNCTIONAL DIAGRAM



GENERAL DESCRIPTION

The SSM-2141 is an integrated differential amplifier intended to receive balanced line inputs in audio applications requiring a high level of noise immunity and optimum common-mode rejection. The SSM-2141 typically achieves 100dB of common-mode rejection (CMR), whereas implementing an op amp with four off-the-shelf precision resistors will typically achieve only 40dB of CMR – inadequate for high-performance audio.

The SSM-2141 achieves low distortion performance by maintaining a large slew rate of 9.5V/μs and high open-loop gain. Distortion is less than 0.002% over the full audio bandwidth. The SSM-2141 complements the SSM-2142 balanced line driver. Together, these devices comprise a fully integrated solution for equivalent transformer balancing of audio signals without the problems of distortion, EMI fields, and high cost.

Additional applications for the SSM-2141 include summing signals, differential preamplifiers, and 600Ω low distortion buffer amplifiers.

ANALOG DEVICES

Balanced Line Driver

SSM2142

FEATURES

Transformer-Like Balanced Output
Drives 10 V RMS Into a 600 Ω Load
Stable When Driving Large Capacitive Loads and Long Cables
Low Distortion
0.006% typ 20 Hz-20 kHz, 10 V RMS into 600 Ω
High Slew Rate
15 V/μs typ
Low Gain Error
(Differential or Single-Ended); 0.7% typ
Outputs Short-Circuit Protected
Available In Space-Saving 8-Pin Mini-DIP Package
Low Cost

APPLICATIONS

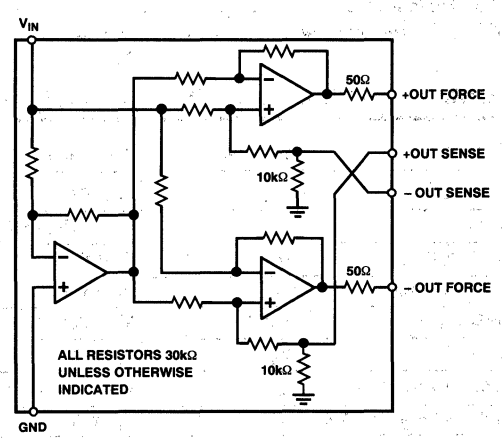
Audio Mix Consoles
Distribution Amplifiers
Graphic and Parametric Equalizers
Dynamic Range Processors
Digital Effects Processors
Telecommunications Systems
Industrial Instrumentation
Hi-Fi Equipment

GENERAL DESCRIPTION

The SSM-2142 is an integrated differential-output buffer amplifier that converts a single-ended input signal to a balanced output signal pair with high output drive. By utilizing low noise thermally matched thin film resistors and high slew rate amplifiers, the SSM-2142 helps maintain the sonic quality of audio systems by eliminating power line hum, RF interference, voltage drops, and other externally generated noise commonly encountered with long audio cable runs. Excellent rejection of common-mode noise and offset errors is achieved by laser trimming of the onboard resistors, assuring high gain accuracy. The carefully designed output stage of the SSM-2142 is capable of driving difficult loads, yielding low-distortion performance despite extremely long cables or loads as low as 600 Ω, and is stable over a wide range of operating conditions.

Based on a cross-coupled, electronically balanced topology, the SSM-2142 mimics the performance of fully balanced transformer-based solutions for line driving. However, the SSM-2142 maintains lower distortion and occupies much less board space than transformers while achieving comparable common-mode rejection performance with reduced parts count.

FUNCTIONAL BLOCK DIAGRAM



The SSM-2142 in tandem with the SSM-2141 differential receiver establishes a complete, reliable solution for driving and receiving audio signals over long cables. The SSM-2141 features an Input Common-Mode Rejection Ratio of 100 dB at 60 Hz. Specifications demonstrating the performance of this typical system are included in the data sheet.

−6 dB Differential Line Receiver

SSM2143

FEATURES

High Common-Mode Rejection
- **DC: 90 dB typ**
- **60 Hz: 90 dB typ**
- **20 kHz: 85 dB typ**

Ultralow THD: 0.0006% typ @ 1 kHz
Fast Slew Rate: 10 V/μs typ
Wide Bandwidth: 7 MHz typ (G = 1/2)
Two Gain Levels Available: G = 1/2 or 2
Low Cost

GENERAL DESCRIPTION

The SSM-2143 is an integrated differential amplifier intended to receive balanced line inputs in audio applications requiring a high level of immunity from common-mode noise. The device provides a typical 90 dB of common-mode rejection (CMR), which is achieved by laser trimming of resistances to better than 0.005%.

Additional features of the device include a slew rate of 10 V/μs and wide bandwidth. Total harmonic distortion (THD) is less than 0.004% over the full audio band, even while driving low impedance loads. The SSM-2143 input stage is designed to handle input signals as large as +28 dBu at G = 1/2. Although primarily intended for G = 1/2 applications, a gain of 2 can be realized by reversing the +IN/−IN and SENSE/REFERENCE connections.

When configured for a gain of 1/2, the SSM-2143 and SSM-2142 Balanced Line Driver provide a fully integrated, unity gain solution to driving audio signals over long cable runs.

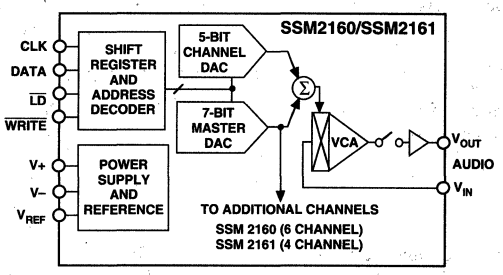
Home THX† System
DSP Soundfield Processors
Automotive Audio Systems
HDTV Audio Systems

FUNCTIONAL BLOCK DIAGRAM



GENERAL DESCRIPTION

The SSM2160 and SSM2161 allow digital control of volume for six and four channels, respectively, with a master level control. In order to avoid "clicking," the device uses high performance voltage controlled amplifiers (VCAs) for the audio signal path. The VCA control port effectively isolates DAC charge injection from the audio path, which is the major contributor to clicking in resistor-ladder type attenuators. Each channel is controlled by a dedicated 5-bit DAC, providing 32 steps of adjustment, plus mute. In addition, a master 7-bit DAC feeds every control port, with 128 steps. Therefore, a balance can be achieved among all channels over a 32-step range, and the master control allows adjustment over its entire range while maintaining the desired channel-to-channel balance. Step sizes are defaulted to 1 dB, but channel sizes can be increased or master sizes decreased by the addition of external resistors. Approximately 80 dB of attenuation and up to 20 dB of gain is possible.

The SSM2160/SSM2161 can operate either single or dual supply, with a total supply voltage range of 8 V to 36 V. An on-chip voltage reference is provided for single-supply applications.

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the SSM2160/SSM2161 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

*XIND = –40°C to +85°C

GENERAL DESCRIPTION

The SSM-2402/2412 are dual analog switches designed specifically for high-performance audio applications. Distortion and noise are negligible over the full audio operating range of 20Hz to 20kHz at signal levels of up to $10V_{RMS}$. The SSM-2402/2412 offer a monolithic integrated alternative to expensive and noisy relays or complex discrete JFET circuits. Unlike conventional general-purpose CMOS switches, the SSM-2402/2412 provide superb fidelity without audio "clicks" during switching.

Conventional TTL or CMOS logic can be used to control the switch state. No external pull-up resistors are needed. A "T" configuration provides superb OFF-isolation and true bilateral operation. The analog inputs and outputs are protected against overload and overvoltage.

An important feature is the guaranteed "break-before-make" for all units, even IC-to-IC. In large systems with multiple switching channels, all separate switching units must open before any switch goes into the ON-state. With the SSM-2402/2412, you can be certain that multiple circuits will all break-before-make.

The SSM-2402/2412 represent a significant step forward in audio switching technology. Distortion and switching noise are significantly reduced in the new SSM-2402/2412 bipolar-JFET switches relative to CMOS switching technology. Based on a new circuit topology that optimizes audio performance, the SSM-2402/2412 make use of a proprietary bipolar-JFET process with thin-film resistor network capability. Nitride capacitors, which are very area efficient, are used for the proprietary ramp generator that controls the switch resistance transition. Very wide bandwidth amplifiers control the gate-to-source voltage over the full audio operating range for each switch. The ON-resistance remains constant with changes in signal amplitude and frequency, thus distortion is very low, less than 0.01% Max.

The SSM-2402 is the first analog switch truly optimized for high-performance audio applications. For broadcasting and other switching applications which require a faster switching time, we recommend the SSM-2412 – a dual analog switch with one-third of the switching time of the SSM-2402.

NOTES:

1. "V_{IL}" is the Logic Control Input.
2. Current tested at $V_{IN} = 0V$. This is the worst case condition.
3. Guaranteed by R_{ON} test condition.
4. Turn-ON Time is measured from the time the logic input reaches the 50% point to the time the output reaches 50% of the final value.
5. Turn-OFF time is measured from the time the logic input reaches the 50% point to the time the output reaches 50% of the initial value.
6. Switch is guaranteed by design to provide break-before-make operation.
7. THD guaranteed by design and dynamic R_{ON} testing.

ANALOG DEVICES

Quad Audio Switch

SSM2404

FEATURES

- "Clickless" Bilateral Audio Switching
- Four SPST Switches in a 20-Pin Package
- Ultralow THD+N: 0.0008% @ 1 kHz (2 V rms, R_L = 100 kΩ)
- Low Charge Injection: 35 pC typ
- High OFF Isolation: −100 dB typ (R_L = 10 kΩ @ 1 kHz)
- Low Crosstalk: −94 dB typ (R_L = 10 kΩ @ 1 kHz)
- Low ON Resistance: 28 Ω typ
- Low Supply Current: 900 μA typ
- Single or Dual Supply Operation: +11 V to +24 V or ±5.5 V to ±12 V
- Guaranteed Break-Before-Make
- TTL and CMOS Compatible Logic Inputs
- Low Cost-Per-Switch

GENERAL DESCRIPTION

The SSM-2404 integrates four SPST analog switches in a single 20-pin package. Developed specifically for high performance audio applications, distortion and noise are negligible over the full operating range of 20 Hz to 20 kHz. With very low charge injection of 35 pC, "clickless" audio switching is possible, even under the most demanding conditions.

Switch control is realized by conventional TTL or CMOS logic. Guaranteed "break-before-make" operation assures that all switches in a large system will open before any switch reaches the ON state.

Single or dual supply operation is possible. Additional features include −100 dB OFF isolation, −94 dB crosstalk and 28 Ω ON resistance. Optional current-mode switching permits an extended signal-handling range. Although optimized for large load impedances, the SSM-2404 maintains good audio performance even under low load impedance conditions.

APPLICATIONS INFORMATION

The SSM-2404 integrates four analog CMOS switches with guaranteed "break-before-make" operation to provide high quality audio switching. Each switch has complementary N-channel and P-channel MOSFETs to allow the analog input voltage range to include the positive and negative rails and improve linearity. In addition, the topology permits fully bilateral switching. When using the SSM-2404 there is full flexibility in configuring the switches. For example, they can be used individually as shown in Figure 20, or as a double-pole, double-throw (DPDT) switch, which is explained later. The SSM-2404 can also be configured as a 4:1 multiplexer, or by using additional packages, as 8:1 or 16:1 and up. The break-before-make feature is guaranteed from part to part allowing such multiple-package applications.

As Figure 20 shows, the SSM-2404 is easy to use, and no additional devices are needed. The load resistors are recommended for improved OFF-isolation and charge injection. The ON resistance of the switch is only 28 Ω typically, which causes very little signal attenuation even with a load resistor.

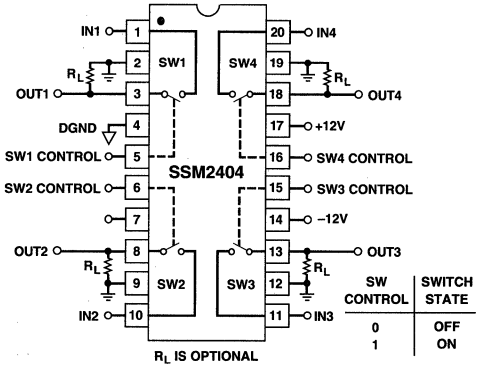

Figure 20. Basic Circuit Configuration

OPTIMIZING PERFORMANCE

As the performance curves show, the switch is optimized for high impedance loads. The distortion performance is at its best when the switch has a load impedance of 100 kΩ or greater as shown in Figure 1. However, even at lower values of load resistances, the 1 kHz distortion performance is still excellent, 0.006% for a 10 kΩ load. The main trade-off with THD is OFF-isolation and crosstalk. This is shown in Figures 10 and 11, again with two different load conditions. As these graphs show, the 10 kΩ load yields approximately a 16 dB improvement in both characteristics.

Thus, the optimum operating point depends on the most critical parameters. When THD is critical then high load impedances should be used; however, when crosstalk and OFF-isolation are critical, lower impedances on the order of 10 kΩ should be used. An additional benefit of using the smaller load resistor is that any charge injected onto the output will be shunted to ground through the resistor. If improved OFF-isolation is needed, the SSM-2402 dual audio switch should be considered with its excellent 120 dB OFF-isolation at 20 kHz.

It is important that all of the AGND pins be connected to the system analog ground. These pins isolate the input and output of each switch. Without connecting these pins, the OFF-isolation will degrade significantly.

DETAILED SWITCH OPERATION

A simplified circuit schematic with the functional sections is shown in Figure 21. The TTL interface has an internally regulated 5 V to ensure TTL logic levels regardless of the supply voltage. The logic threshold is with respect to the DGND pin, which can be offset. For example, if DGND is connected to the negative supply, then the SSM-2404 will operate with negative rail logic. The interface shifts the control logic down to the negative supply and inverts it to drive N1.

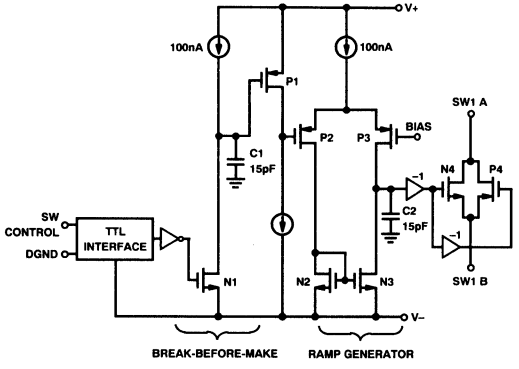

Figure 21. Simplified Schematic

N1 in combination with C1 and the 100 nA current source provides the break-before-make operation of the switch. When the switch is on, N1 is off and C1 is charged up to the positive rail. However, when the SW CONTROL is turned off, then the gate of N1 is pulled high. This turns N1 on, providing a low impedance path to quickly discharge C1 to the negative rail, which quickly "breaks" the switch. On the other hand, when the SW CONTROL goes high again, the gate of N1 is pulled low, turning it off. This leaves C1 to be slowly charged up to the positive rail by the 100 nA current source. The difference in the discharge and charging times ensures break-before-make operation, even from device to device.

The voltage on C1 is inverted by P1 to drive the ramp generator differential pair, consisting of P2, P3 and N2, N3. This differential pair steers the 100 nA of tail current to either charge or discharge C2. As discussed above, when the switch is on, C1 is charged up to the positive rail. P1 inverts this, putting a low voltage equivalent to the negative supply on the gate of P2. The BIAS voltage is approximately equal to the midpoint of the two supply voltages. Thus, when P2 is pulled down, it is turned on and P3 is off. All of the 100 nA flows through N2 and is mirrored by N3. Thus, the 100 nA discharges C2 through N3. When C2 is pulled low, the inverter turns N4 on by pulling its gate high, and the second inverter turns P4 on. To turn the switch off the gate of P2 is pulled above the BIAS so that all 100 nA charges C2 through P3. This is then inverted to turn off N4 and P4.

The internal ramp has rise and fall times on the order of a few milliseconds which is sped-up by the inverters. As the gate voltages of N4 and P4 are changing, the ON resistance of each switch is ramping from its OFF state to 28 Ω and vice versa. The actual rise and fall times are shown in Figures 18 and 19 for a 5 kΩ load. These times are significantly slower than typical switches, minimizing the SSM-2404's charge injection and giving it "clickless" performance.

DOUBLE-POLE DOUBLE-THROW SWITCH

The SSM-2404 is ideal as a one-chip solution for a stereo switch. The schematic in Figure 22 shows the typical configuration. This circuit will select one of two stereo sources, channel A or B. The switch controls for the left and right input of each channel are tied together so that both will be turned on or off simultaneously. An inverter is inserted between the channel A and B controls so that only one logic signal is needed. The outputs can be configured many different ways, such as an inverting or noninverting amplifier stage, and the 10 kΩ load resistors are added to improve the OFF-isolation. The performance of this stereo switch is equivalent to each individual switch, yielding a high quality audio switch that is virtually transparent to the signal.

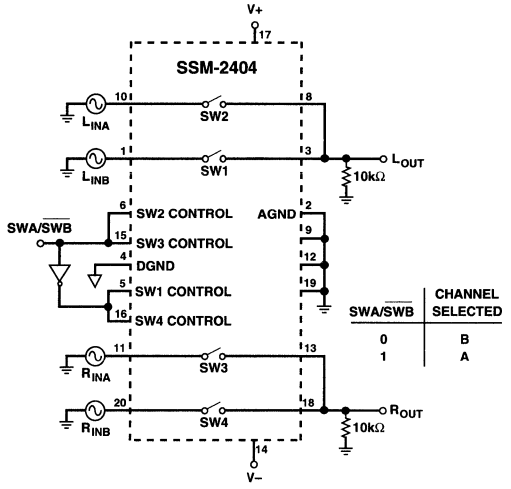

Figure 22. Double-Pole, Double-Throw Stereo Switch

VIRTUAL GROUND SWITCHING

The SSM-2404 was built on a CMOS process with a 24 V operating limit for the total supply voltage across the part. This leads to a corresponding limit on the analog voltage range. However, to achieve larger signal swings, the SSM-2404 should be configured in the virtual ground mode. As shown in Figure 23, the output of the SSM-2404 is connected to the inverting input of an amplifier. Since the noninverting input is grounded, the SSM-2404 will also be biased at ground, and large voltage swings on the circuit's input will not significantly change the voltage on the switch. The only limitation is that the current through the switch needs to be less than ±10 mA, and the voltage range is limited only by the op amp and its supply voltages.

The circuit was tested with an SSM-2131 high slew rate audio amplifier and the results are shown in Figures 24 and 25. This configuration yields excellent THD performance that is primarily determined by the amplifier. Also, the headroom is now +24 dBu (0 dBu = 0.775 V rms), which is due to the amplifier's output voltage swing. Thus, even though the SSM-2404 has a ±12 V limitation on its supplies, it can be used in systems with much higher voltage ranges. For example, the double-pole double-throw switch from Figure 22 can be reconfigured in the virtual ground mode to allow higher voltage swings, as shown in Figure 26. This application realizes the excellent performance of Figures 24 and 25 while providing a low cost switching solution.

Clock Recovery and Data Retiming Phase-Locked Loop

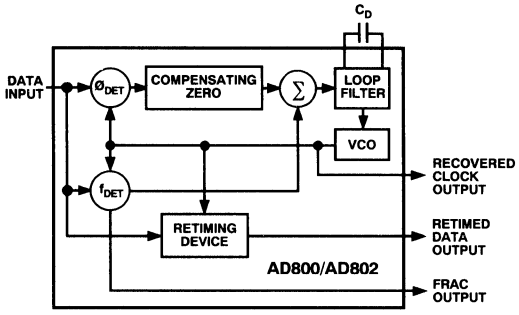
AD800/AD802*

FEATURES

Standard Products
- **44.736 Mbps – DS-3**
- **51.84 Mbps – STS-1**
- **155.52 Mbps – STS-3 or STM-1**

Accepts NRZ Data, No Preamble Required
Recovered Clock and Retimed Data Outputs
Phase-Locked Loop Type Clock Recovery – No Crystal Required
Random Jitter: 20° Peak-to-Peak
Pattern Jitter: Virtually Eliminated
10KH ECL Compatible
Single Supply Operation: −5.2 V or +5 V
Wide Operating Temperature Range: −40°C to +85°C

FUNCTIONAL BLOCK DIAGRAM



PRODUCT DESCRIPTION

The AD800 and AD802 employ a second order phase-locked loop architecture to perform clock recovery and data retiming on Non-Return to Zero, NRZ, data. This architecture is capable of supporting data rates between 20 Mbps and 160 Mbps. The products described here have been defined to work with standard telecommunications bit rates. 45 Mbps DS-3 and 52 Mbps STS-1 are supported by the AD800-45 and AD800-52 respectively. 155 Mbps STS-3 or STM-1 are supported by the AD802-155.

Unlike other PLL-based clock recovery circuits, these devices do not require a preamble or an external VCXO to lock onto input data. The circuit acquires frequency and phase lock using two control loops. The frequency acquisition control loop initially acquires the clock frequency of the input data. The phase-lock loop then acquires the phase of the input data, and ensures that the phase of the output signals track changes in the phase of the input data. The loop damping of the circuit is dependent on the value of a user selected capacitor; this defines jitter peaking performance and impacts acquisition time. The devices exhibit 0.08 dB jitter peaking, and acquire lock on random or scrambled data within 4×10^5 bit periods when using a damping factor of 5.

During the process of acquisition the frequency detector provides a Frequency Acquisition (FRAC) signal which indicates that the device has not yet locked onto the input data. This signal is a series of pulses which occur at the points of cycle slip between the input data and the synthesized clock signal. Once the circuit has acquired frequency lock no pulses occur at the FRAC output.

***Protected by U.S. Patent No. 5,027,085.**

The inclusion of a precisely trimmed VCO in the device eliminates the need for external components for setting center frequency, and the need for trimming of those components. The VCO provides a clock output within ±20% of the device center frequency in the absence of input data.

The AD800 and AD802 exhibit virtually no pattern jitter, due to the performance of the patented phase detector. Total loop jitter is 20° peak-to-peak. Jitter bandwidth is dictated by mask programmable fractional loop bandwidth. The AD800, used for data rates < 90 Mbps, has been designed with a nominal loop bandwidth of 0.1% of the center frequency. The AD802, used for data rates in excess of 90 Mbps, has a loop bandwidth of 0.08% of center frequency.

All of the devices operate with a single +5 V or −5.2 V supply.

GLOSSARY

Maximum and Minimum Specifications
Maximum and minimum specifications result from statistical analyses of measurements on multiple devices and multiple test systems. Typical specifications indicate mean measurements. Maximum and minimum specifications are calculated by adding or subtracting an appropriate guardband from the typical specification. Device-to-device performance variation and test system-to-test system variation contribute to each guardband.

Nominal Center Frequency
This is the frequency that the VCO will operate at with no input signal present and the loop damping capacitor, C_D, shorted.

Tracking Range
This is the range of input data rates over which the PLL will remain in lock.

Capture Range
This is the range of input data rates over which the PLL can acquire lock.

Static Phase Error
This is the steady-state phase difference, in degrees, between the recovered clock sampling edge and the optimum sampling instant, which is assumed to be halfway between the rising and falling edges of a data bit. Gate delays between the signals that define static phase error, and IC input and output signals prohibit direct measurement of static phase error.

Data Transition Density, ρ
This is a measure of the number of data transitions, from "0" to "1" and from "1" to "0," over many clock periods. ρ is the ratio ($0 \leq \rho \leq 1$) of data transitions to clock periods.

Jitter
This is the dynamic displacement of digital signal edges from their long term average positions, measured in degrees rms, or Unit Intervals (UI). Jitter on the input data can cause dynamic phase errors on the recovered clock sampling edge. Jitter on the recovered clock causes jitter on the retimed data.

Output Jitter
This is the jitter on the retimed data, in degrees rms, due to a specific pattern or some psuedo-random input data sequence (PRN Sequence).

Jitter Tolerance
Jitter tolerance is a measure of the PLL's ability to track a jittery input data signal. Jitter on the input data is best thought of as phase modulation, and is usually specified in unit intervals.

15

ORDERING GUIDE

Device	Center Frequency	Fractional Loop Bandwidth	Description	Operating Temperature	Package Option*
AD800-45BQ	44.736 MHz	0.1%	20-Pin Cerdip	−40°C to +85°C	Q-20
AD800-52BR	51.84 MHz	0.1%	20-Pin Plastic SOIC	−40°C to +85°C	R-20
AD802-155BR	155.52 MHz	0.08%	20-Pin Plastic SOIC	−40°C to +85°C	R-20
AD802-155KR	155.52 MHz	0.08%	20-Pin Plastic SOIC	0°C to +70°C	R-20

*For outline information see Package Information section.

The PLL must provide a clock signal which tracks this phase modulation in order to accurately retime jittered data. In order for the VCO output to have a phase modulation which tracks the input jitter, some modulation signal must be generated at the output of the phase detector (see Figure 21). The modulation output from the phase detector can only be produced by a phase error between the data input and the clock input. Hence, the PLL can never perfectly track jittered data. However, the magnitude of the phase error depends on the gain around the loop. At low frequencies the integrator provides very high gain, and thus very large jitter can be tracked with small phase errors between input data and recovered clock. At frequencies closer to the loop bandwidth, the gain of the integrator is much smaller, and thus less input jitter can be tolerated. The PLL data output will have a bit error rate less than 1×10^{-10} when in lock and retiming input data that has the specified jitter applied to it.

Jitter Transfer
The PLL exhibits a low-pass filter response to jitter applied to its input data.

Bandwidth
This describes the frequency at which the PLL attenuates sinusoidal input jitter by 3 dB.

Peaking
This describes the maximum jitter gain of the PLL in dB.

Damping Factor, ζ
ζ describes how the PLL will track an input signal with a phase step. A greater value of ζ corresponds to less overshoot in the PLL response to a phase step. ζ is a standard constant in second order feedback systems.

Acquisition Time
This is the transient time, measured in bit periods, required for the PLL to lock on input data from its free-running state.

Symmetry
Symmetry is calculated as (100 × on time)/period, where on time equals the time that the clock signal is greater than the midpoint between its "0" level and its "1" level.

Bit Error Rate vs. Signal-to-Noise Ratio
The AD800 and AD802 were designed to operate with standard ECL signal levels at the data input. Although not recommended, smaller input signals are tolerable. Figure 8, 14, and 20 show the bit error rate performance versus input signal-to-noise ratio for input signal amplitudes of full 900 mV ECL, and decreased amplitudes of 80 mV and 20 mV. Wideband amplitude noise is summed with the data signals as shown in Figure 2. The full ECL and 80 mV signals give virtually indistinguishable results. The 20 mV signals also provide adequate performance when in lock, but signal acquisition may be impaired.

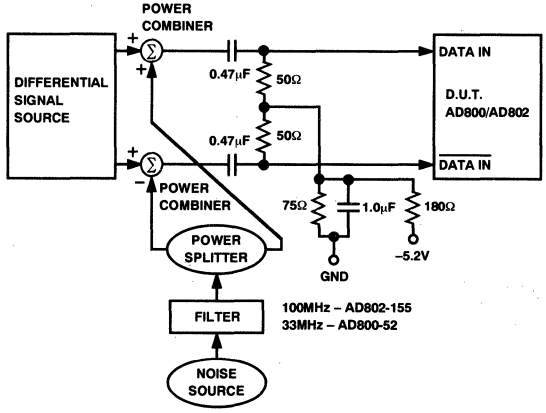

Figure 2. Bit Error Rate vs. Signal-to-Noise Ratio Test: Block Diagram

USING THE AD800 AND THE AD802 SERIES

Ground Planes
Use of one ground plane for connections to both analog and digital grounds is recommended. Output signal sensitivity to power supply noise (PECL configuration, Figure 22) is less using one ground plane than when using separate analog and digital ground planes.

Power Supply Connections
Use of a 10 μF tantalum capacitor between V_{EE} and ground is recommended.

Use of 0.1 μF ceramic capacitors between IC power supply or substrate pins and ground is recommended. Power supply decoupling should take place as close to the IC as possible. Refer to schematics, Figure 22 and Figure 26, for advised connections.

Sensitivity of IC output signals (PECL configuration, Figure 22) to high frequency power supply noise (at 2× the nominal data rate) can be reduced through the connection of signals AV_{CC} and V_{CC1}, and the addition of a bypass network. The type of bypass network to consider depends on the noise tolerance required. The more complex bypass network schemes tolerate greater power supply noise levels. Refer to Figures 23 and 24 for bypassing schemes and power supply sensitivity curves.

Transmission Lines
Use of 50 Ω transmission lines are recommended for DATAIN, CLKOUT, DATAOUT, and FRAC signals.

Terminations
Termination resistors should be used for DATAIN, CLKOUT, DATAOUT, and FRAC signals. Metal, thick film, 1% tolerance resistors are recommended. Termination resistors for the DATAIN signals should be placed as close as possible to the DATAIN pins.

Connections form V_{EE} to lead resistors for DATAIN, DATAOUT, FRAC, and CLKOUT signals should be individual, not daisy chained. This will avoid crosstalk on these signals.

Loop Damping Capacitor, C_D
A ceramic capacitor may be used for the loop damping capacitor.

Input Buffer
Use of an input buffer, such as a 10H116 Line Receiver IC, is suggested for an application where the DATAIN signals do not come directly from an ECL gate, or where noise immunity on the DATAIN signals is an issue.

THEORY OF OPERATION

The AD800 and AD802 are phase-locked loop circuits for recovery of clock from NRZ data. The architecture uses a frequency detector to aid initial frequency acquisition, refer to Figure 21 for a block diagram. Note the frequency detector is always in the circuit. When the PLL is locked, the frequency error is zero and the frequency detector has no further effect. Since the frequency detector is always in circuit, no control functions are needed to initiate acquisition or change mode after acquisition. The frequency detector also supplies a frequency acquisition (FRAC) output to indicate when the loop is acquiring lock. During the frequency acquisition process the FRAC output is a series of pulses of width equal to the period of the VCO. These pulses occur on the cycle slips between the data frequency and the VCO frequency. With a maximum density (1010 . . .) data pattern, every cycle slip will produce a pulse at FRAC. However, with random data, not every cycle slip produces a pulse. The density of pulses at FRAC increases with the density of data transitions. The probability that a cycle slip will produce a pulse increases as the frequency error approaches zero. After the frequency error has been reduced to zero, the FRAC output will have no further pulses. At this point the PLL begins the process of phase acquisition, with a settling time of roughly 2000 bit periods. Valid retimed data can be guaranteed by waiting 2000 bit periods after the last FRAC pulse has occurred.

Jitter caused by variations of density of data transitions (pattern jitter) is virtually eliminated by use of a new phase detector (patented). Briefly, the measurement of zero phase error does not cause the VCO phase to increase to above the average run rate set by the data frequency. The jitter created by a $2^7 - 1$ pseudo-random code is 1/2 degree, and this is small compared to random jitter.

The jitter bandwidth for the AD802-155 is 0.08% of the center frequency. This figure is chosen so that sinusoidal input jitter at 130 kHz will be attenuated by 3 dB. The jitter bandwidths of the AD800-45 and AD800-52 are 0.1% of the respective center frequencies. The jitter bandwidth of the AD800 or the AD802 is mask programmable from 0.01% to 1% of the center frequency. A device with a very low loop bandwidth (0.01% of the center frequency) could effectively filter (clean up) a jittery timing reference. Consult the factory if your application requires a special loop bandwidth.

The damping ratio of the phase-locked loop is user programmable with a single external capacitor. At 155 MHz a damping ratio of 10 is obtained with a 0.22 μF capacitor. More generally, the damping ratio scales as $1.7 \times \sqrt{f_{DATA} \times C_D}$. At 155 MHz a damping ratio of 1 is obtained with a 2.2 nF capacitor. A lower damping ratio allows a faster frequency acquisition; generally the acquisition time scales directly with the capacitor value. However, at damping ratios approaching one, the acquisition time no longer scales directly with the capacitor value. The acquisition time has two components: frequency acquisition and phase acquisition. The frequency acquisition always scales with capacitance, but the phase acquisition is set by the loop bandwidth of the PLL and is independent of the damping ratio. Thus, the 0.08% fractional loop bandwidth sets a minimum acquisition time of 15,000 bit periods. Note the acquisition time for a damping factor of 1 is specified as 15,000 bit periods. This comprises 13,000 bit periods for frequency acquisition and 2,000 periods for phase acquisition. Compare this to the 400,000 bit periods acquisition time specified for a damping ratio of 5; this consists entirely of frequency acquisition, and the 2,000 bit periods of phase acquisition is negligible.

While lower damping ratio affords faster acquisition, it also allows more peaking in the jitter transfer response (jitter peaking). For example, with a damping ratio of 10 the jitter peaking is 0.02 dB, but with a damping factor of 1, the peaking is 2 dB.

+5 V Powered RS-232/RS-422 Transceiver

AD7306

FEATURES

RS-232 and RS-422 on One Chip
Single +5 V Supply
0.1 μF Capacitors
Short Circuit Protection
Excellent Noise Immunity
Low Power BiCMOS Technology
High Speed, Low Skew RS-422 Operation
−40°C to +85°C Operation

APPLICATIONS

DTE-DCE Interface
Packet Switching
Local Area Networks
Data Concentration
Data Multiplexers
Integrated Services Digital Network (ISDN)

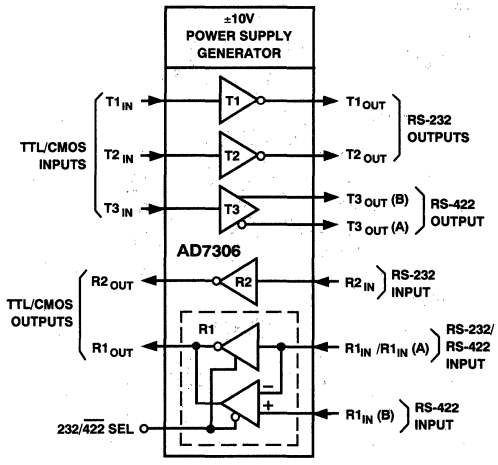
GENERAL DESCRIPTION

The AD7306 line driver/receiver is a 5 V monolithic product which provides an interface between TTL signal levels and dual standard EIA RS-232/RS-422 signal levels. The part contains two RS-232 drivers, one RS-422 driver, one RS-232 receiver, and one receiver path which can be configured either as RS-232 or as RS-422.

An internal charge pump voltage converter facilitates operation from a single +5 V power supply. The internal charge pump generates ±10 V levels allowing RS-232 output levels to be developed without the need for external bipolar power supplies.

A highly efficient charge pump design allows operation using non polarized, miniature 0.1 μF capacitors. This gives a considerable saving in printed circuit board space over conventional products which can use up to 10 μF capacitors. The charge pump output voltages may also be used to power external circuitry which requires dual supplies.

FUNCTIONAL BLOCK DIAGRAM



The RS-232 channels are suitable for communications rates up to 100 kHz and the RS-422 channels are suitable for high speed communications up to 5 MHz. The RS-422 transmitter complementary outputs are closely matched and feature low timing skew between the complementary outputs. This is often an essential requirement to meet tight system timing specifications.

All inputs feature ESD protection, all driver outputs feature high source and sink current capability and are internally protected against short circuits on the outputs. An epitaxial layer is used to guard against latch-up.

The part is available in a 24-lead SOIC and 24-pin plastic DIP packages.

*Stresses above those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. This is a stress rating only and functional operation of the device at these or any other conditions above those listed in the operational sections of this specification is not implied. Exposure to absolute maximum ratings for extended periods of time may affect device reliability.

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the AD7306 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

PIN FUNCTION DESCRIPTION

SOIC Pin	DIP Pin	Mnemonic	Function
1	19	V+	Internally Generated Positive Supply (+9 V nominal). A 0.1 μF capacitor must be connected between this pin and GND.
2, 3	20, 22	C1+, C1−	External Capacitor 1 Terminals. A 0.1 μF capacitor must be connected between these pins.
4	23	$R2_{IN}$	RS-232 Receiver R2 Input. This input accepts RS-232 input voltages.
5	24	$T1_{OUT}$	RS-232 Transmitter (Driver) T1 Output (Typically ±7.5 V).
6	1	$T2_{OUT}$	RS-232 Transmitter (Driver) T2 Output (Typically ±7.5 V).
7	2	V_{CC}	Power Supply Input (5 V ± 5%).
8	3	$R1_{IN}$ (B)	RS-422 Receiver R1, Differential Input B.
9	4	$R1_{IN}/R1_{IN}$ (A)	Receiver R1 Input. May be configured to accept either single ended RS-232 levels or differential RS-422 levels. It is configured using the 232/$\overline{422}$ SEL pin.
10	5	$T3_{OUT}$ (B)	RS-422 Transmitter (Driver) T3, Differential Output B.
11	6	$T3_{OUT}$ (A)	RS-232 Transmitter (Driver) T3, Differential Output A.
12, 13	16, 21	NC	No Connect Pins.
14, 18	7, 11	GND	Ground Pin. Must be connected to 0 V.
15	8	232/$\overline{422}$ SEL	Select Input. This input configures Receiver R1 to accept either RS-232 or RS-422 signal levels. A Logic 1 on this input selects 232 operation while a Logic 0 selects 422 operation.
16	9	$T3_{IN}$	TTL/CMOS Input to the RS-422 Transmitter T3.
17	10	$R1_{OUT}$	TTL/CMOS Output from Receiver R1.
19	12	$T2_{IN}$	TTL/CMOS Input to RS-232 Transmitter T2.
20	13	$T1_{IN}$	TTL/CMOS Input to RS-232 Transmitter T1.
21	14	$R2_{OUT}$	TTL/CMOS Output from Receiver R2.
22, 23	15, 17	C2+, C2−	External Capacitor 2 Terminals. A 0.1 μF capacitor must be connected between these pins.
24	18	V−	Internally Generated Negative Supply (−9 V nominal). A 0.1 μF capacitor must be connected between this pin and GND

GENERAL DESCRIPTION

The AD7306 drivers/receivers provide an interface which is compatible with RS-232/RS-422 standard interfaces. As both standards are widely accepted it is often necessary to provide an interface which is compatible with both. The AD7306 is ideally suited to this type of application as both standards may be met using a single package. This part contains two RS-232 drivers, one RS-422 driver, one RS-232 receiver, and one receiver path which can be configured as either RS-232 or RS-422. This receiver is configured using the 232/$\overline{422}$ SEL pin.

This part also contains an internal charge pump voltage converter which facilitates operation using a single +5 V power supply.

Charge Pump DC-DC Voltage Generator

The charge pump voltage generator uses a switched capacitor technique to develop ±10 V levels from an input +5 V supply. A highly efficient charge pump design coupled with a high frequency internal oscillator permit operation using four 0.1 μF capacitors.

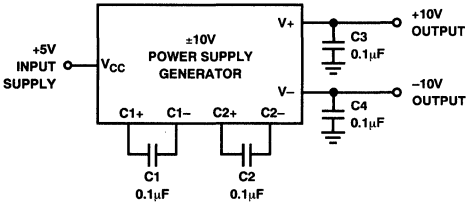

Figure 7. Charge Pump Voltage Generator

Capacitors C1 and C2 act as charge storage capacitors while C3 and C4 provide output smoothing. For correct operation all four capacitors must be included. Either polarized or nonpolarized capacitors may be used for C1–C4. If a polarized type is used, then the correct polarity should be observed. This may be ignored with nonpolarized type capacitors.

The charge pump output voltages, V+ and V−, are used internally to power the RS-232 transmitters. This permits RS-232 output levels to be developed on the RS-232 transmitter outputs. The charge pump output voltages may also be used to power external circuitry if the current requirements are small. Please refer to the Typical Performance Characteristics.

The generator rise time after power up is 200 μs typical. This time is necessary to completely charge the storage capacitors in the charge pump. Therefore, RS-232 data transmission should not be initiated until this time has elapsed after switch on. This will ensure that valid data is always transmitted.

RS-232 Drivers

The RS-232 drivers in the AD7306 meet the EIA RS-232 specifications. The drivers are inverting level shifters which convert TTL/CMOS levels into RS-232 output levels. The input switching threshold is typically 1.3 V. With a typical RS-232 load, the output levels are ±7.5 V. Under worst case load conditions, the drivers are guaranteed to provide ±5 V which meets the minimum RS-232 requirement. The output slew rate is internally limited to <30 V/μs without the need for an external slew-limiting capacitor. Short circuit protection is also provided which prevents damage in the event of output fault conditions. Active current limiting is used which limits the output short circuit current to less than 12 mA in the event of an output fault. This type of current limiting does not degrade the output voltage swing under normal loading conditions as would be the case with conventional passive limiting.

The powered-down output impedance is typically 10 MΩ. This is considerably larger than the 300 Ω minimum value required by the RS-232 specification. It provides additional protection under fault conditions where another powered-up transmitter output is inadvertently shorted to the powered-down device.

RS-232 Receivers

The receivers are inverting level shifters which accept RS-232 input levels (±3 V to ±15 V) and translates them into 5 V TTL/CMOS levels. The input switching thresholds are 0.8 V minimum and 2.4 V maximum which are well within the RS-232 requirement of ±3 V. Internal 5 kΩ pull-down resistors to GND are provided on the receiver inputs. This ensures that an unconnected input will be interpreted as a low level giving a Logic "1" on the TTL/CMOS output. Excellent noise immunity is achieved by the use of hysteresis and internal filtering circuitry. The filter rejects noise glitches of up to 0.5 μs in duration.

RS-422 Driver

The RS-422 driver on the AD7306 accepts a TTL/CMOS input and translates it into a differential RS-422 level signal. The input switching threshold is typically 1.3 V. The unloaded output differential voltage is typically ±5 V (see Typical Performance Characteristics). Short circuit protection is provided on the output which limits the current to less than 150 mA.

RS-422 Receiver

The RS-422 receiver on the AD7306 accepts a differential input signal and translates it into a TTL/CMOS output level. The input resistance on both differential inputs is 5 kΩ typical. With the receiver inputs unconnected (floating), internal biasing ensures that the receiver output is a Logic "1."

Excellent noise immunity and high transmission speed is achieved using the differential configuration.

Single-Ended Data Transmission

Single-ended interfaces are used for low speed, short distance communications such as from a computer terminal to a printer. A single line is used to carry the signal. Various standards have been developed to standardize the communication link, the most popular of these being the RS-232. The RS-232 standard was introduced in 1962 by the EIA and has been widely used throughout the industry. The standard has been revised several times, and the current revision is known as EIA-232E. The RS-232 standard is suitable for single-ended data transmission at relatively slow data rates over short distances. A typical RS-232 interface is shown in Figure 14.

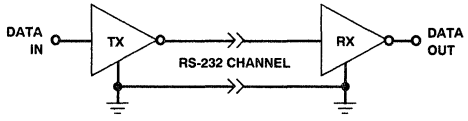

Figure 14. Single-Ended RS-232 Interface

Differential Data Transmission

When transmitting at high data rates, over long distances and through noisy environments, single-ended data transmission is often inadequate. In this type of application, differential data transmission offers superior performance. Differential transmission uses two signal lines to transmit data. It rejects ground shifts and is insensitive to noise signals which appear as common mode voltages on the transmission lines. To accommodate faster data communication, the differential RS-422 standard was developed. Therefore, it can be used to reliably transmit data at higher speeds and over longer distances than single-ended transmission. A typical RS-422 interface is shown in Figure 15.

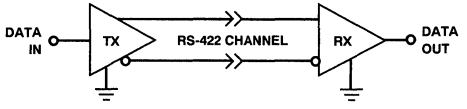

Figure 15. Differential RS-422 Interface

Table I. Comparison of RS-232 and RS-422 Interface Standards

Instruments

GENERAL DESCRIPTION

The ADM202/ADM203 is a two-channel RS-232 line driver/receiver pair designed to operate from a single +5 V power supply. A highly efficient on-chip charge pump design permits RS-232 levels to be developed using charge pump capacitors as small as 0.1 µF. The capacitors are internal to the package on the ADM203 so no external capacitors are required. These converters generate ±10 V RS-232 output levels.

The ADM202/ADM203 meets or exceeds the EIA-232-E and V.28 specifications. Fast driver slew rates permit operation up to 120 kB while high drive currents allows for extended cable lengths.

An epitaxial BiCMOS construction minimizes power consumption to 10 mW and also guards against latch-up. Overvoltage protection is provided allowing the receiver inputs to withstand continuous voltages in excess of ±30 V. In addition, all pins contain ESD protection to levels greater than 2 kV.

The ADM202 is available in 16-lead DIP and both narrow and wide SOIC packages. The ADM203 is available in a 20-pin DIP package.

PIN FUNCTION DESCRIPTION

Mnemonic	Function
V_{CC}	Power Supply Input 5 V ± 10%.
V+	Internally Generated Positive Supply (+10 V nominal).
V–	Internally Generated Negative Supply (–10 V nominal).
GND	Ground Pin. Must be connected to 0 V.
C1+	ADM202 External Capacitor, (+ terminal) is connected to this pin. ADM203: The capacitor is connected internally and no external capacitor is required.
C1–	ADM202 External Capacitor, (– terminal) is connected to this pin. ADM203: The capacitor is connected internally and no external capacitor is required.
C2+	ADM202 External Capacitor, (+ terminal) is connected to this pin. ADM203: The capacitor is connected internally and no external capacitor is required.
C2–	ADM202 External Capacitor, (– terminal) is connected to this pin. ADM203: The capacitor is connected internally and no external capacitor is required.
T_{IN}	Transmitter (Driver) Inputs. These inputs accept TTL/CMOS levels. An internal 400 kΩ pull-up resistor to V_{CC} is connected on each input.
T_{OUT}	Transmitter (Driver) Outputs. These are RS-232 levels (typically ±10 V).

R_{IN}	Receiver Inputs. These inputs accept RS-232 signal levels. An internal 5 kΩ pull-down resistor to GND is connected on each of these inputs.
R_{OUT}	Receiver Outputs. These are TTL/CMOS levels.

GENERAL INFORMATION

The ADM202/ADM203 is an RS-232 drivers/receivers designed to solve interface problems by meeting the EIA-232E specifications while using a single digital +5 V supply. The EIA standard requires transmitters that will deliver ±5 V minimum on the transmission channel and receivers that can accept signal levels down to ±3 V. The parts achieve this by integrating step up voltage converters and level shifting transmitters and receivers onto the same chip. CMOS technology is used to keep the power dissipation to an absolute minimum.

The ADM203 uses internal capacitors and, therefore, no external capacitors are required.

The ADM202 contains an internal voltage doubler and a voltage inverter which generates ±10 V from the +5 V input. External 0.1 μF capacitors are required for the internal voltage converter.

The ADM202/ADM203 is a modification, enhancement and improvement to the AD230–AD241 family and derivatives thereof. It is essentially plug-in compatible and does not have materially different applications.

CIRCUIT DESCRIPTION

The internal circuitry consists of three main sections. These are

(a) A Charge Pump Voltage Converter

(b) RS-232 to TTL/CMOS Receivers

(c) TTL/CMOS to RS-232 Transmitters

Charge Pump DC-DC Voltage Converter

The charge pump voltage converter consists of an oscillator and a switching matrix. The converter generates a ±10 V supply from the input 5 V level. This is done in two stages using a switched capacitor technique as illustrated below. First, the 5 V input supply is doubled to 10 V using capacitor C1 as the charge storage element. The 10 V level is then inverted to generate −10 V using C2 as the storage element.

Capacitors C3 and C4 are used to reduce the output ripple. Their values are not critical and can be reduced if higher levels of ripple are acceptable. The charge pump capacitors C1 and C2 may also be reduced at the expense of higher output impedance on the V+ and V− supplies. On the ADM203, all capacitors C1 to C4 are molded into the package.

The V+ and V− supplies may also be used to power external circuitry if the current requirements are small.

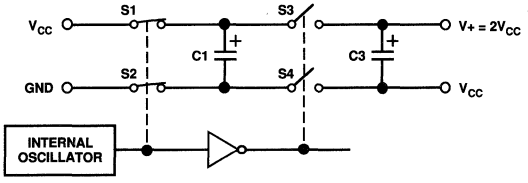

Figure 2. Charge Pump Voltage Doubler

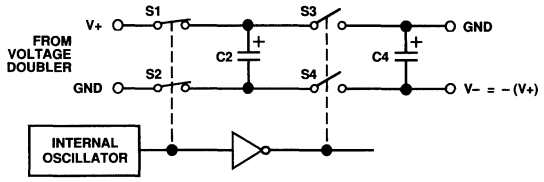

Figure 3. Charge Pump Voltage Inverter

Transmitter (Driver) Section

The drivers convert TTL/CMOS input levels into EIA-232-E output levels. With V_{CC} = +5 V and driving a typical EIA-232-E load, the output voltage swing is ±9 V. Even under worst case conditions the drivers are guaranteed to meet the ±5 V EIA-232-E minimum requirement.

The input threshold levels are both TTL and CMOS compatible with the switching threshold set at $V_{CC}/4$. With a nominal V_{CC} = 5 V the switching threshold is 1.25 V typical. Unused inputs may be left unconnected, as an internal 400 kΩ pull-up resistor pulls them high forcing the outputs into a low state.

As required by the EIA-232-E standard the slew rate is limited to less than 30 V/μs without the need for an external slew limiting capacitor and the output impedance in the power-off state is greater than 300 Ω.

Receiver Section

The receivers are inverting level shifters that accept EIA-232-E input levels (±5 V to ±15 V) and translate them into 5 V TTL/CMOS levels. The inputs have internal 5 kΩ pull-down resistors to ground and are also protected against overvoltages of up to ±30 V. The guaranteed switching thresholds are 0.8 V minimum and 2.4 V maximum which are well within the ±3 V EIA-232 requirement. The low level threshold is deliberately positive as it ensures that an unconnected input will be interpreted as a low level.

The receivers have Schmitt trigger input with a hysteresis level of 0.5 V. This ensures error free reception both for noisy inputs and for inputs with slow transition times.

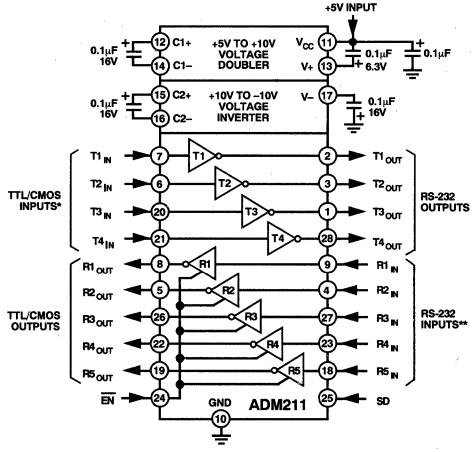
ADM205–ADM211/ADM213

FEATURES
0.1 μF to 10 μF Capacitors
120 kB/s Data Rate
2 Receivers Active in Shutdown (ADM213)
On-Board DC-DC Converters
±9 V Output Swing with +5 V Supply
Low Power (15 mW)
Low Power Shutdown ≤5 μW
±30 V Receiver Input Levels
Latch-Up FREE
Plug-In Upgrade for MAX205-211/213

APPLICATIONS
Computers
Peripherals
Modems
Printers
Instruments

TYPICAL OPERATING CIRCUIT



*INTERNAL 400kΩ PULL-UP RESISTOR ON EACH TTL/CMOS INPUT
**INTERNAL 5kΩ PULL-DOWN RESISTOR ON EACH RS-232 INPUT

GENERAL DESCRIPTION

The ADM2xx family of line drivers/receivers is intended for all EIA-232-E and V.28 communications interfaces, especially in applications where ±12 V is not available. The ADM205, ADM206, ADM211 and ADM213 feature a low power shutdown mode which reduces power dissipation to less than 5 μW making them ideally suited for battery powered equipment. The ADM205 does not require any external components and is particularly useful in applications where printed circuit board space is critical. The ADM213 has an active-low shutdown and an active-high receiver enable control. Two receivers of the ADM213 remain active during shutdown. This feature is useful for ring indicator monitoring.

All members of the ADM2xx family, except the ADM209, include two internal charge pump voltage converters which allow operation from a single +5 V supply. These converters convert the +5 V input power to the ±10 V required for RS-232 output levels. The ADM209 is designed to operate from +5 V and +12 V supplies. An internal +12 V to −12 V charge pump voltage converter generates the −12 V supply.

Table I. Selection Table

Part Number	Power Supply Voltage	No. of RS-232 Drivers	No. of RS-232 Receivers	External Capacitors	Low Power Shutdown (SD)	TTL Three-State $\overline{EN}$	No. of Receivers Active in Shutdown
ADM205	+5 V	5	5	None	Yes	Yes	0
ADM206	+5 V	4	3	4	Yes	Yes	0
ADM207	+5 V	5	3	4	No	No	0
ADM208	+5 V	4	4	4	No	No	0
ADM209	+5 V & +9 V to +13.2 V	3	5	2	No	Yes	0

PIN FUNCTION DESCRIPTION

Mnemonic	Function
V_{CC}	Power Supply Input 5 V ± 10% (+5 V ± 5% ADM205).
V+	Internally generated positive supply (+10 V nominal) on all parts except ADM209.
	ADM209 requires external 9 V to 13.2 V supply.
V−	Internally generated negative supply (−10 V nominal).
GND	Ground pin. Must be connected to 0 V.
C+	(ADM209 only) External capacitor (+ terminal) is connected to this pin.
C−	(ADM209 only) External capacitor (− terminal) is connected to this pin.
C1+	(ADM206, ADM207, ADM208, ADM211, ADM213) External capacitor (+ terminal) is connected to this pin.
C1−	(ADM206, ADM207, ADM208, ADM211, ADM213) External capacitor (− terminal) is connected to this pin.
C2+	(ADM206, ADM207, ADM208, ADM211, ADM213) External capacitor (+ terminal) is connected to this pin.
C2−	(ADM206, ADM207, ADM208, ADM211, ADM213) External capacitor (− terminal) is connected to this pin.
T_{IN}	Transmitter (Driver) Inputs. These inputs accept TTL/CMOS levels. An internal 400 kΩ pull-up resistor to V_{CC} is connected on each input.
T_{OUT}	Transmitter (Driver) Outputs. These are RS-232 levels (typically ±10 V).
R_{IN}	Receiver Inputs. These inputs accept RS-232 signal levels. An internal 5 kΩ pull-down resistor to GND is connected on each input.
R_{OUT}	Receiver Outputs. These are TTL/CMOS levels.
$\overline{EN}$/EN	Enable Input. Active low on ADM205, ADM206, ADM209, ADM211. Active high on ADM213. This input is used to enable/disable the receiver outputs. With $\overline{EN}$ = Low (EN = High ADM213), the receiver outputs are enabled. With $\overline{EN}$ =High (EN = low ADM213), the outputs are placed in a high impedance state. This facility is useful for connecting to microprocessor systems.
SD/$\overline{SD}$	Shutdown Input. Active high on ADM205, ADM206, ADM211. Active low on ADM213. With SD = high on the ADM205, ADM206, ADM211, the charge pump is disabled, the receiver outputs are placed in a high impedance state and the driver outputs are turned off. With $\overline{SD}$ low on the ADM213, the charge pump is disabled, the driver outputs are turned off and all receivers except R4 and R5 are placed in a high impedance state. In shutdown, the power consumption reduces to 5 μW.
NC	No Connect. No connections are required to this pin.

Table II. ADM205, ADM206, ADM211 Truth Table

SD	$\overline{EN}$	Status	Transmitters T1–T5	Receivers R1–R5
0	0	Normal Operation	Enabled	Enabled

GENERAL INFORMATION

The ADM205–ADM211 and ADM213 family of RS-232 drivers/receivers are designed to solve interface problems by meeting the EIA-232-E specifications while using a single digital +5 V supply. The EIA-232-E standard requires transmitters which will deliver ±5 V minimum on the transmission channel and receivers which can accept signal levels down to ±3 V. The ADM205–ADM211 and ADM213 meet these requirements by integrating step up voltage converters and level shifting transmitters and receivers onto the same chip. CMOS technology is used to keep the power dissipation to an absolute minimum. A comprehensive range of transmitter/receiver combinations is available to cover most communications needs. The ADM205–ADM211 and ADM213 are modifications, enhancements and improvements to the AD230–AD241 family and derivatives thereof. They are essentially plug-in compatible and do not have materially different applications.

The ADM205, ADM206, ADM211, and ADM213 are particularly useful in battery powered systems as they feature a low power shutdown mode which reduces power dissipation to less than 5 µW.

The ADM205 is designed for applications where space saving is important as the charge pump capacitors are molded into the package.

The ADM209 includes only a negative charge pump converter and are intended for applications where a positive 12 V is available.

To facilitate sharing a common line or for connection to a microprocessor data bus the ADM205, ADM206, ADM209, ADM211 and ADM213 feature an enable ($\overline{EN}$) function. When disabled, the receiver outputs are placed in a high impedance state.

CIRCUIT DESCRIPTION

The internal circuitry in the ADM205–ADM211 and ADM213 consists of three main sections. These are:

(a) A charge pump voltage converter
(b) RS-232 to TTL/CMOS receivers
(c) TTL/CMOS to RS-232 transmitters

Charge Pump DC-DC Voltage Converter

The charge pump voltage converter consists of an oscillator and a switching matrix. The converter generates a ±10 V supply from the input 5 V level. This is done in two stages using a switched capacitor technique as illustrated in Figures 23 and 24. First, the 5 V input supply is doubled to 10 V using capacitor C1 as the charge storage element. The 10 V level is then inverted to generate −10 V using C2 as the storage element.

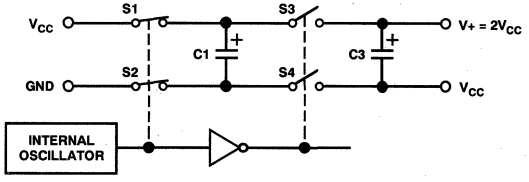

Figure 23. Charge-Pump Voltage Doubler

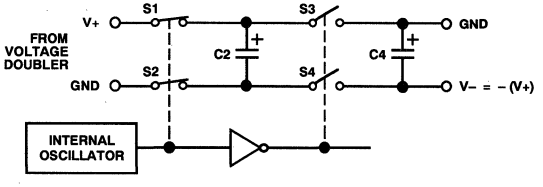

Figure 24. Charge-Pump Voltage Inverter

Capacitors C3 and C4 are used to reduce the output ripple. Their values are not critical and can be reduced if higher levels of ripple are acceptable. The charge pump capacitors C1 and C2 may also be reduced at the expense of higher output impedance on the V+ and V− supplies.

The V+ and V− supplies may also be used to power external circuitry if the current requirements are small.

Transmitter (Driver) Section

The drivers convert TTL/CMOS input levels into EIA-232-E output levels. With V_{CC} = +5 V and driving a typical EIA-232-E load, the output voltage swing is ±9 V. Even under worst case conditions the drivers are guaranteed to meet the ±5 V EIA-232-E minimum requirement.

The input threshold levels are both TTL and CMOS compatible with the switching threshold set at $V_{CC}/4$. With a nominal V_{CC} = 5 V the switching threshold is 1.25 V typical. Unused inputs may be left unconnected, as an internal 400 kΩ pull-up resistor pulls them high forcing the outputs into a low state.

As required by the EIA-232-E standard, the slew rate is limited to less than 30 V/μs without the need for an external slew limiting capacitor and the output impedance in the power-off state is greater than 300 Ω.

Receiver Section

The receivers are inverting level shifters which accept EIA-232-E input levels (±5 V to ±15 V) and translate them into 5 V TTL/CMOS levels. The inputs have internal 5 kΩ pull-down resistors to ground and are also protected against overvoltages of up to ±30 V. The guaranteed switching thresholds are 0.8 V minimum and 2.4 V maximum which are well within the ±3 V EIA-232-E requirement. The low level threshold is deliberately positive as it ensures that an unconnected input will be interpreted as a low level.

The receivers have Schmitt trigger inputs with a hysteresis level of 0.5 V. This ensures error-free reception for both noisy inputs and for inputs with slow transition times.

Shutdown (SD)

The ADM205, ADM206, ADM211 and ADM213 feature a control input which may be used to disable the part and reduce the power consumption to less than 5 μW. This is very useful in battery operated systems. During shutdown the charge pump is turned off, the transmitters are disabled and all receivers except R4 and R5 on the ADM213 are put into a high-impedance disabled state. Receivers R4 and R5 on the ADM213 remain enabled during shutdown. This feature allows monitoring external activity such as ring indicator monitoring while the device is in a low power shutdown mode. The shutdown control input is active high on all parts except the ADM213 where it is active low. Refer to Tables II and III.

Enable Input

The ADM205, ADM209, ADM211, and ADM213 feature an enable input used to enable or disable the receiver outputs. The enable input is active low on the ADM205, ADM209, ADM211 and active-high on the ADM213. Refer to Tables II and III. When disabled, all receiver outputs are placed in a high impedance state. This function allows the outputs to be connected directly to a microprocessor data bus. It can also be used to allow receivers from different devices to share a common data line. The timing diagram for the enable function is shown in Figure 25.

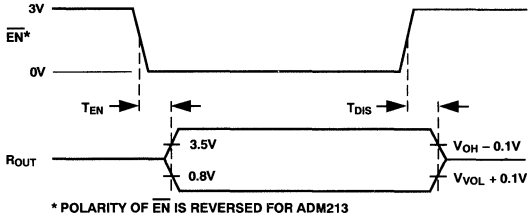

Figure 25. Enable Timing

APPLICATION HINTS

Driving Long Cables

In accordance with the EIA-232-E standard, long cables are permissible provided that the total load capacitance does not exceed 2500 pF. For longer cables which do exceed this, then it is possible to trade off baud rate vs. cable length. Large load capacitances cause a reduction in slew rate, and hence the maximum transmission baud rate is decreased. The ADM205–ADM211 and ADM213 are designed so that the slew rate reduction with increasing load capacitance is minimized.

For the receivers, it is important that a high level of noise immunity be inbuilt so that slow rise and fall times do not cause multiple output transitions as the signal passes slowly through the transition region. The ADM205–ADM211 and ADM213 have 0.5 V of hysteresis to guard against this. This ensures that, even in noisy environments, error-free reception can be achieved.

High Baud Rate Operation

The ADM205–ADM211 and ADM213 feature high slew rates permitting data transmission at rates well in excess of the EIA-232-E specification. The drivers maintain ±5 V signal levels at data rates up to 120-kB/s under worst-case loading conditions.

High Speed, +5 V, 0.1 µF CMOS RS-232 Drivers/Receivers

ADM222/ADM232A/ADM242*

FEATURES
200 kB/s Transmission Rate
Small (0.1 µF) Charge Pump Capacitors
Single 5 V Power Supply
Meets All EIA-232-E and V.28 Specifications
Two Drivers and Two Receivers
On-Board DC-DC Converters
±9 V Output Swing with +5 V Supply
±30 V Receiver Input Levels
Pin Compatible with MAX222/MAX232A/MAX242

APPLICATIONS
Computers
Peripherals
Modems
Printers
Instruments

GENERAL DESCRIPTION

The ADM222, ADM232A, ADM242 are a family of high speed RS-232 line drivers/receivers offering transmission rates up to 200 kB/s. Operating from a single +5 V power supply, a highly efficient on-chip charge pump using small (0.1 µF) external capacitors allows RS-232 bipolar levels to be developed. Two RS-232 drivers and two RS-232 receivers are provided on each device.

The devices are fabricated on BiCMOS, an advanced mixed technology process which combines low power CMOS with high speed bipolar circuitry. This allows for transmission rates up to 200 kB/s yet minimizes the quiescent power supply current to under 5 mA.

The ADM232A is a pin-compatible, high speed upgrade for the AD232 and for the ADM232L. It is available in 16-pin DIP and in both narrow and wide surface mount (SOIC) packages.

The ADM222 contains an additional shutdown ($\overline{SHDN}$) function which may be used to disable the device thereby reducing the supply current to 0.1 µA. During shutdown, all transmit/receive functions are disabled. The ADM222 is available in 18-pin DIP and in a wide surface mount (SOIC) package.

The ADM242 combines both shutdown ($\overline{SHDN}$) and enable ($\overline{EN}$) functions. The shutdown function reduces the supply curent to 0.1 mA. During shutdown, the transmitters are disabled but the receivers continue to operate normally. The enable function allows the receiver outputs to be disabled thereby facilitating sharing a common bus. The ADM242 is available in 18-pin DIP and in a wide surface mount (SOIC) package.

PIN FUNCTION DESCRIPTION

Mnemonic	Function
V_{CC}	Power Supply Input, +5 V ± 10%.
V+	Internally generated positive supply (+10 V nominal).
V–	Internally generated negative supply (–10 V nominal).
GND	Ground Pin. Must be connected to 0 V.
C1+	External capacitor 1, (+ terminal) is connected to this pin.
C1–	External capacitor 1, (– terminal) is connected to this pin.
C2+	External capacitor 2, (+ terminal) is connected to this pin.
C2–	External capacitor 2, (– terminal) is connected to this pin.
T_{IN}	Transmitter (Driver) Inputs. These inputs accept TTL/CMOS levels. An internal 400 kΩ pull-up resistor to V_{CC} is connected on each input.
T_{OUT}	Transmitter (Driver) Outputs. These are RS-232 levels (typically ±9 V).
R_{IN}	Receiver Inputs. These inputs accept RS-232 signal levels. An internal 5 kΩ pull-down resistor to GND is connected on each of these inputs.
R_{OUT}	Receiver Outputs. These are TTL/CMOS levels.
NC	No Connect. No connections are required to this pin.
$\overline{EN}$	(ADM242 Only) Active Low Digital Input. May be used to enable or disable (three-state) both receiver outputs.
$\overline{SHDN}$	(ADM222 & ADM242) Active Low Digital Input. May be used to disable the device so that the power consumption is minimized. On the ADM222 all drivers and receivers are disabled. On the ADM242 the drivers are disabled but the receivers remain enabled.

GENERAL INFORMATION

The ADM222/ADM232A/ADM242 are high speed RS-232 drivers/receivers requiring a single digital +5 V supply. The RS-232 standard requires transmitters that will deliver ±5 V minimum on the transmission channel and receivers that can accept signal levels down to ±3 V. The parts achieve this by integrating step up voltage converters and level shifting transmitters and receivers onto the same chip. CMOS technology is used to keep the power dissipation to an absolute minimum. All devices contains an internal charge pump voltage doubler and a voltage inverter that generates ±10 V from the +5 V input. Four external 0.1 µF capacitors are required for the internal charge pump voltage converter.

The ADM222/ADM232A/ADM242 is a modification, enhancement and improvement to the AD230-AD241 family and derivatives thereof. It is essentially plug-in compatible and does not have materially different applications.

CIRCUIT DESCRIPTION

The internal circuitry consists of four main sections. These are:

A Charge Pump Voltage Converter
TTL/CMOS to RS-232 Transmitters
RS-232 to TTL/CMOS Receivers
Enable and Shutdown Functions.

Charge Pump DC-DC Voltage Converter

The Charge Pump Voltage converter consists of an oscillator and a switching matrix. The converter generates a ±10 V supply from the input 5 V level. This is done in two stages using a switched capacitor technique. The 5 V input supply is doubled to 10 V using capacitor C1 as the charge storage element. The –10 V level is also generated from the input 5 V supply using C1 and C2 as the storage elements.

Capacitors C3 and C4 are used to reduce the output ripple. Their values are not critical and can be reduced if higher levels of ripple are acceptable. The charge pump capacitors C1 and C2 may also be reduced at the expense of higher output impedance on the V+ and V– supplies.

The V+ and V– supplies may also be used to power external circuitry if the current requirements are small. Please refer to the typical performance characteristics which shows the V+, V– output voltage vs. current.

In the shutdown mode the charge pump is disabled and V+ decays to V_{CC} while V– decays to 0 V.

Transmitter (Driver) Section

The Drivers convert TTL/CMOS input levels into RS-232 output levels. With V_{CC} = +5 V and driving a typical RS-232 load, the output voltage swing is ±9 V. Even under worst case conditions the drivers are guaranteed to meet the ±5 V RS-232 minimum requirement.

The input threshold levels are both TTL and CMOS compatible with the switching threshold set at $V_{CC}/4$. With a nominal V_{CC} = 5 V the switching threshold is 1.25 V typical. Unused inputs may be left unconnected, as an internal 400 kΩ pull- up resistor pulls them high forcing the outputs into a low state.

As required by the RS-232 standard, the slew rate is limited to less than 30 V/µs without the need for an external slew limiting capacitor, and the output impedance in the power-off state is greater than 300 Ω.

Receiver Section

The receivers are inverting level shifters which accept RS-232 input levels (±3 V to ±15 V) and translate them into 5 V TTL/CMOS levels. The inputs have internal 5 kΩ pull-down resistors to ground and are also protected against overvoltages of up to ±30 V. The guaranteed switching thresholds are 0.8 V minimum and 2.4 V maximum which are well within the ±3 V RS-232 requirement. The low level threshold is deliberately positive as it ensures that an unconnected input will be interpreted as a low level.

The receivers have Schmitt trigger input with a hysteresis level of 0.5 V. This ensures error free-reception for both noisy inputs and for inputs with slow transition times

Enable and Shutdown Functions

On the ADM222, both receivers are fully disabled during shutdown.

On the ADM242, both receivers continue to operate normally. This function is useful for monitoring activity so that when it occurs, the device can be taken out of the shutdown mode.

The ADM242 also contains a receiver enable function ($\overline{EN}$) which can be used to fully disable the receivers, independent of $\overline{SHDN}$.

APPLICATIONS INFORMATION

A selection of typical operating circuits is shown in Figures 13 to 19.

ANALOG DEVICES

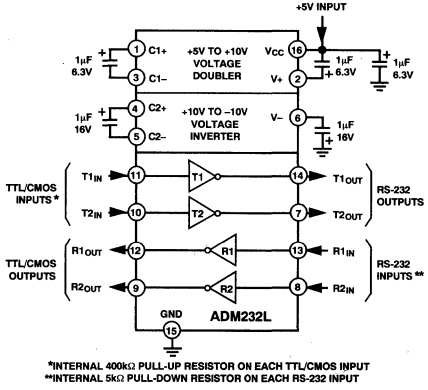
+5 V Powered CMOS RS-232 Drivers/Receivers

ADM223/ADM230L–ADM241L

FEATURES
Single 5 V Power Supply
Meets All EIA-232-E and V.28 Specifications
120 kB/s Data Rate
On-Board DC-DC Converters
±9 V Output Swing with +5 V Supply
Small 1 μF Capacitors
Low Power Shutdown ≤1 μA
Receivers Active in Shutdown (ADM223)
ESD > 2 kV
±30 V Receiver Input Levels
Latch-Up FREE
Plug-In Upgrade for MAX223/230-241
Plug-In Upgrade for AD230–AD241

APPLICATIONS
Computers
Peripherals
Modems
Printers
Instruments

ADM232L TYPICAL OPERATING CIRCUIT



GENERAL DESCRIPTION

The ADM2xx family of line drivers/receivers is intended for all EIA-232-E and V.28 communications interfaces, especially in applications where ±12 V is not available. The ADM223, ADM230L, ADM235L, ADM236L and ADM241L feature a low power shutdown mode which reduces power dissipation to less than 5 μW making them ideally suited for battery powered equipment. Two receivers remain enabled during shutdown on the ADM223. The ADM233L and ADM235L do not require any external components and are particularly useful in applications where printed circuit board space is critical.

All members of the ADM230L family, except the ADM231L and the ADM239L, include two internal charge pump voltage converters which allow operation from a single +5 V supply. These converters convert the +5 V input power to the ±10 V required for RS-232 output levels. The ADM231L and ADM239L are designed to operate from +5 V and +12 V supplies. An internal +12 V to −12 V charge pump voltage converter generates the −12 V supply.

The ADM2xxL is an enhanced upgrade for the AD2xx family featuring lower power consumption, faster slew rate and operation with smaller (1 μF) capacitors.

PIN FUNCTION DESCRIPTION

Mnemonic	Function
V_{CC}	Power Supply Input 5 V ± 10% (+5 V ± 5% ADM233L, ADM235L).
V+	Internally generated positive supply (+10 V nominal) on all parts except ADM231L and ADM239L.
	ADM231L, ADM239L requires external 7.5 V to 13.2 V supply.
V−	Internally generated negative supply (−10 V nominal).
GND	Ground pin. Must be connected to 0 V.
C+	(ADM231L and ADM239L only). External capacitor (+ terminal) is connected to this pin.
C−	(ADM231L and ADM239L only). External capacitor (− terminal) is connected to this pin.
C1+	(ADM230L, ADM232L, ADM234L, ADM236L, ADM237L, ADM238L, ADM241L) External capacitor (+ terminal) is connected to this pin.
	(ADM233L) The capacitor is connected internally and no external connection to this pin is required.
C1−	(ADM230L, ADM232L, ADM234L, ADM236L, ADM237L, ADM238L, ADM241L) External capacitor (− terminal) is connected to this pin.
	(ADM233L) The capacitor is connected internally and no external connection to this pin is required.
C2+	(ADM230L, ADM232L, ADM234L, ADM236L, ADM237L, ADM238L, ADM241L) External capacitor (+ terminal) is connected to this pin.
	(ADM233L) Internal capacitor connections, Pins 11 and 15 must be connected together.
C2−	(ADM230L, ADM232L, ADM234L, ADM236L, ADM237L, ADM238L, ADM241L) External capacitor (− terminal) is connected to this pin.
	(ADM233L) Internal capacitor connections, Pins 10 and 16 must be connected together.
T_{IN}	Transmitter (Driver) Inputs. These inputs accept TTL/CMOS levels. An internal 400 kΩ pull-up resistor to V_{CC} is connected on each input.
T_{OUT}	Transmitter (Driver) Outputs. These are RS-232 levels (typically ±10 V).
R_{IN}	Receiver Inputs. These inputs accept RS-232 signal levels. An internal 5 kΩ pull-down resistor to GND is connected on each input.
R_{OUT}	Receiver Outputs. These are TTL/CMOS levels.
$\overline{EN}$/EN	Enable Input. Active low on ADM235L, ADM236L, ADM239L, ADM241L. Active high ADM223. This input is used to enable/disable the receiver outputs. With $\overline{EN}$ = low (EN = high ADM223), the receiver outputs are enabled. With $\overline{EN}$ = high (EN = low ADM223), the outputs are placed in a high impedance state. This facility is useful for connecting to microprocessor systems.
SD/$\overline{SD}$	Shutdown Input. Active high on ADM235L, ADM236L, ADM241L. Active low on ADM223. With SD = high on the ADM235L, ADM236L, ADM241L, the charge pump is disabled, the receiver outputs are placed in a high impedance state and the driver outputs are turned off. With $\overline{SD}$ low on the ADM223, the charge pump is disabled, the driver outputs are turned off and all receivers except R4 and R5 are placed in a high impedance state. In shutdown, the power consumption reduces to 5 μW.
NC	No Connect. No connections are required to this pin.

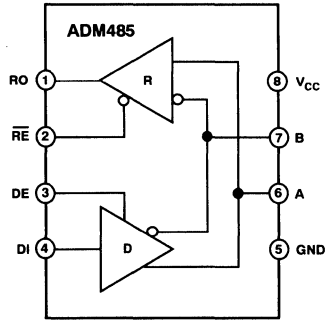
+5 V Low Power EIA RS-485 Transceiver

ADM485

FEATURES
Meets EIA RS-485 Standard
5 Mb/s Data Rate
Single +5 V Supply
−7 V to +12 V Bus Common-Mode Range
High Speed, Low Power BiCMOS
Thermal Shutdown Protection
Short Circuit Protection
Zero Skew Driver
Driver Propagation Delay: 10 ns
Receiver Propagation Delay: 25 ns
High Z Outputs with Power Off
Superior Upgrade for LTC485

APPLICATIONS
Low Power RS-485 Systems
DTE-DCE Interface
Packet Switching
Local Area Networks
Data Concentration
Data Multiplexers
Integrated Services Digital Network (ISDN)

FUNCTIONAL BLOCK DIAGRAM



DESCRIPTION

The ADM485 is a differential line transceiver suitable for high speed bidirectional data communication on multipoint bus transmission lines. It is designed for balanced data transmission and complies with both EIA Standards RS-485 and RS-422. The part contains a differential line driver and a differential line receiver. Both the driver and the receiver may be enabled independently. When disabled, the outputs are tristated.

The ADM485 operates from a single +5 V power supply. Excessive power dissipation caused by bus contention or by output shorting is prevented by a thermal shutdown circuit. This feature forces the driver output into a high impedance state if during fault conditions a significant temperature increase is detected in the internal driver circuitry.

Up to 32 transceivers may be connected simultaneously on a bus, but only one driver should be enabled at any time. It is important therefore that the remaining disabled drivers do not load the bus. To ensure this, the ADM485 driver features high output impedance when disabled and also when powered down. This minimizes the loading effect when the transceiver is not being utilized. The high impedance driver output is maintained over the entire common-mode voltage range from −7 V to +12 V.

The receiver contains a fail safe feature which results in a logic high output state if the inputs are unconnected (floating).

The ADM485 is fabricated on BiCMOS, an advanced mixed technology process combining low power CMOS with fast switching bipolar technology. All inputs and outputs contain protection against ESD; all driver outputs feature high source and sink current capability. An epitaxial layer is used to guard against latch-up.

The ADM485 features extremely fast switching speeds. Minimal driver propagation delays permit transmission at data rates up to 5 Mbits/s while low skew minimizes EMI interference.

The part is fully specified over the commercial and industrial temperature range and is available in an 8-pin DIL/ SOIC package.

ADM485—SPECIFICATIONS (V_{CC} = +5 V ± 5%. All specifications T_{MIN} to T_{MAX} unless otherwise noted.)

PIN FUNCTION DESCRIPTION

Pin	Mnemonic	Function
1	RO	Receiver Output. When enabled if A > B by 200 mV, then RO = High. If A < B by 200 mV, then RO = Low.
2	$\overline{RE}$	Receiver Output Enable. A low level enables the receiver output, RO. A high level places it in a high impedance state.
3	DE	Driver Output Enable. A high level enables the driver differential outputs, A and B. A low level places it in a high impedance state.
4	DI	Driver Input. When the driver is enabled a logic Low on DI forces A low and B high while a logic High on DI forces A high and B low.
5	GND	Ground Connection, 0 V.
6	A	Noninverting Receiver Input A/Driver Output A.
7	B	Inverting Receiver Input B/Driver Output B.
8	V_{CC}	Power Supply, 5 V ± 5%.

*For outline information see Package Information section.

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the ADM485 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

APPLICATIONS INFORMATION

Differential Data Transmission

Differential data transmission is used to reliably transmit data at high rates over long distances and through noisy environments. Differential transmission nullifies the effects of ground shifts and noise signals which appear as common-mode voltages on the line. There are two main standards approved by the Electronics Industries Association (EIA) which specify the electrical characteristics of transceivers used in differential data transmission.

The RS-422 standard specifies data rates up to 10 MBaud and line lengths up to 4000 ft. A single driver can drive a transmission line with up to 10 receivers.

In order to cater for true multipoint communications, the RS-485 standard was defined. This standard meets or exceeds all the requirements of RS-422 but also allows for up to 32 drivers and 32 receivers to be connected to a single bus. An extended common-mode range of −7 V to +12 V is defined. The most significant difference between RS-422 and RS-485 is the fact that the drivers may be disabled thereby allowing more than one (32 in fact) to be connected to a single line. Only one driver should be enabled at time, but the RS-485 standard contains additional specifications to guarantee device safety in the event of line contention.

Cable and Data Rate

The transmission line of choice for RS-485 communications is a twisted pair. Twisted pair cable tends to cancel common-mode noise and also causes cancellation of the magnetic fields generated by the current flowing through each wire, thereby, reducing the effective inductance of the pair.

The ADM485 is designed for bidirectional data communications on multipoint transmission lines. A typical application showing a multipoint transmission network is illustrated in Figure 26. An RS-485 transmission line can have as many as 32 transceivers on the bus. Only one driver can transmit at a particular time but multiple receivers may be enabled simultaneously.

As with any transmission line, it is important that reflections are minimized. This may be achieved by terminating the extreme ends of the line using resistors equal to the characteristic impedance of the line. Stub lengths of the main line should also be kept as short as possible. A properly terminated transmission line appears purely resistive to the driver.

Thermal Shutdown

The ADM485 contains thermal shutdown circuitry which protects the part from excessive power dissipation during fault conditions. Shorting the driver outputs to a low impedance source can result in high driver currents. The thermal sensing circuitry detects the increase in die temperature and disables the driver outputs. The thermal sensing circuitry is designed to disable the driver outputs when a die temperature of 150°C is reached. As the device cools, the drivers are re-enabled at 140°C.

Propagation Delay

The ADM485 features very low propagation delay ensuring maximum baud rate operation. The driver is well balanced ensuring distortion free transmission.

Another important specification is a measure of the skew between the complementary outputs. Excessive skew impairs the noise immunity of the system and increases the amount of electromagnetic interference (EMI).

Receiver Open-Circuit Fail Safe

The receiver input includes a fail-safe feature which guarantees a logic high on the receiver when the inputs are open circuit or floating.

Table III. Comparison of RS-422 and RS-485 Interface Standards

Specification	RS-422	RS-485
Transmission Type	Differential	Differential
Maximum Cable Length	4000 ft.	4000 ft.
Minimum Driver Output Voltage	±2 V	±1.5 V
Driver Load Impedance	100 Ω	54 Ω
Receiver Input Resistance	4 kΩ min	12 kΩ min
Receiver Input Sensitivity	±200 mV	±200 mV
Receiver Input Voltage Range	−7 V to +7 V	−7 V to +12 V
No of Drivers/Receivers Per Line	1/10	32/32

Microprocessor Supervisory Circuits

ADM690–ADM695

FEATURES

Superior Upgrade for MAX690–MAX695
Specified Over Temperature
Low Power Consumption (5 mW)
Precision Voltage Monitor
Reset Assertion Down to 1 V V_{CC}
Low Switch On-Resistance 1.5 Ω Normal, 20 Ω in Backup
High Current Drive (100 mA)
Watchdog Timer—100 ms, 1.6 s, or Adjustable
600 nA Standby Current
Automatic Battery Backup Power Switching
Extremely Fast Gating of Chip Enable Signals (5 ns)
Voltage Monitor for Power Fail

APPLICATIONS

Microprocessor Systems
Computers
Controllers
Intelligent Instruments
Automotive Systems

GENERAL DESCRIPTION

The ADM690–ADM695 family of supervisory circuits offers complete single chip solutions for power supply monitoring and battery control functions in microprocessor systems. These functions include μP reset, backup battery switchover, watchdog timer, CMOS RAM write protection, and power failure warning. The complete family provides a variety of configurations to satisfy most microprocessor system requirements.

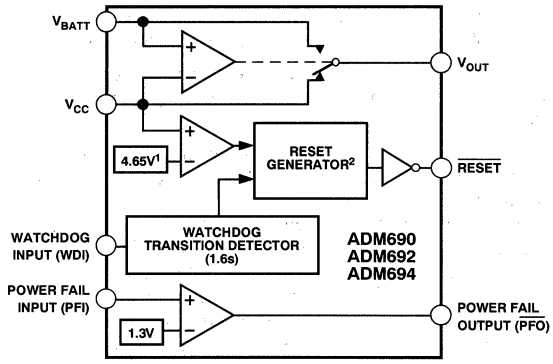
The ADM690, ADM692 and ADM694 are available in 8-pin DIP packages and provide:

1. Power-on reset output during power-up, power-down and brownout conditions. The $\overline{\text{RESET}}$ output remains operational with V_{CC} as low as 1 V.
2. Battery backup switching for CMOS RAM, CMOS microprocessor or other low power logic.
3. A reset pulse if the optional watchdog timer has not been toggled within a specified time.
4. A 1.3 V threshold detector for power fail warning, low battery detection, or to monitor a power supply other than +5 V.

The ADM691, ADM693 and ADM695 are available in 16-pin DIP and small outline packages and provide three additional functions:

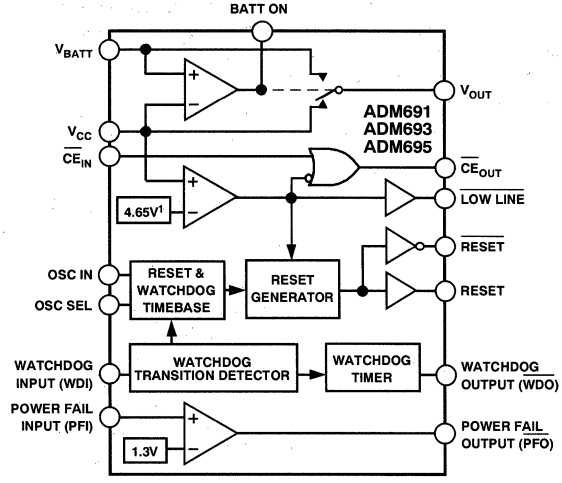
1. Write protection of CMOS RAM or EEPROM.
2. Adjustable reset and watchdog timeout periods.
3. Separate watchdog timeout, backup battery switchover, and low V_{CC} status outputs.

FUNCTIONAL BLOCK DIAGRAMS



[1]VOLTAGE DETECTOR = 4.65V (ADM690, ADM694)
4.40V (ADM692)

[2]RESET PULSE WIDTH = 50ms (ADM690, ADM692)
200ms (ADM694)



[1]VOLTAGE DETECTOR = 4.65V (ADM691, ADM695)
4.40V (ADM693)

The ADM690–ADM695 family is fabricated using an advanced epitaxial CMOS process combining low power consumption (5 mW), extremely fast Chip Enable gating (5 ns) and high reliability. $\overline{\text{RESET}}$ assertion is guaranteed with V_{CC} as low as 1 V. In addition, the power switching circuitry is designed for minimal voltage drop thereby permitting increased output current drive of up to 100 mA without the need for an external pass transistor.

This is an abridged data sheet. To obtain the most recent version or complete data sheet, call our fax retrieval system at 1-800-446-6212.

ADM694AQ	−40°C to +85°C	Q-8
ADM694SQ	−55°C to +125°C	Q-8
ADM695AN	−40°C to +85°C	N-16
ADM695AR	−40°C to +85°C	R-16
ADM695AQ	−40°C to +85°C	Q-16
ADM695SQ	−55°C to +125°C	Q-16

*For outline information see Package Information section.

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the ADM690–ADM695 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

PIN FUNCTION DESCRIPTION

Mnemonic	Function
V_{CC}	Power Supply Input: +5 V Nominal.
V_{BATT}	Backup Battery Input. Connect to Ground if a backup battery is not used.
V_{OUT}	Output Voltage, V_{CC} or V_{BATT} is internally switched to V_{OUT} depending on which is at the highest potential. V_{OUT} can supply up to 100 mA to power CMOS RAM. Connect V_{OUT} to V_{CC} if V_{OUT} and V_{BATT} are not used.
GND	0 V. Ground reference for all signals.
$\overline{RESET}$	Logic Output. $\overline{RESET}$ goes low if 1. V_{CC} falls below the Reset Threshold 2. V_{CC} falls below V_{BATT} 3. The watchdog timer is not serviced within its timeout period. The reset threshold is typically 4.65 V for the ADM690/ADM691/ADM694/ADM695 and 4.4 V for the ADM692 and ADM693. $\overline{RESET}$ remains low for 50 ms (ADM690/ADM691/ADM692/ADM693) or 200 ms (ADM694/ADM695) after V_{CC} returns above the threshold. $\overline{RESET}$ also goes low for 50 (200) ms if the watchdog timer is enabled but not serviced within its timeout period. The $\overline{RESET}$ pulse width can be adjusted on the ADM691/ADM693/ADM695 as shown in Table I. The $\overline{RESET}$ output has an internal 3 μA pull up, and can either connect to an open collector Reset bus or directly drive a CMOS gate without an external pull-up resistor.
WDI	Watchdog Input. WDI is a three level input. If WDI remains either high or low for longer than the watchdog timeout period, $\overline{RESET}$ pulses low and WDO goes low. The timer resets with each transition on the WDI line. The watchdog timer may be disabled if WDI is left floating or is driven to midsupply.
PFI	Power Fail Input. PFI is the noninverting input to the Power Fail Comparator When PFI is less than 1.3 V, $\overline{PFO}$ goes low. Connect PFI to GND or V_{OUT} when not used.
$\overline{PFO}$	Power Fail Output. $\overline{PFO}$ is the output of the Power Fail Comparator. It goes low when PFI is less than 1.3 V. The comparator is turned off and $\overline{PFO}$ goes low when V_{CC} is below V_{BATT}.
$\overline{CE}_{IN}$	Logic Input. The input to the $\overline{CE}$ gating circuit. Connect to GND or V_{OUT} if not used.
$\overline{CE}_{OUT}$	Logic Output. $\overline{CE}_{OUT}$ is a gated version of the $\overline{CE}_{IN}$ signal. $\overline{CE}_{OUT}$ tracks $\overline{CE}_{IN}$ when V_{CC} is above the reset threshold. If V_{CC} is below the reset threshold, $\overline{CE}_{OUT}$ is forced high. See Figures 5 and 6.
BATT ON	Logic Output. BATT ON goes high when V_{OUT} is internally switched to the V_{BATT} input. It goes low when V_{OUT} is internally switched to V_{CC}. The output typically sinks 35 mA and can directly drive the base of an external PNP transistor to increase the output current above the 100 mA rating of V_{OUT}.
$\overline{LOW\ LINE}$	Logic Output. $\overline{LOW\ LINE}$ goes low when V_{CC} falls below the reset threshold. It returns high as soon as V_{CC} rises above the reset threshold.
RESET	Logic Output. RESET is an active high output. It is the inverse of $\overline{RESET}$.
OSC SEL	Logic Oscillator Select Input. When OSC SEL is unconnected (floating) or driven high, the internal oscillator sets the reset active time and watchdog timeout period. When OSC SEL is low, the external oscillator input, OSC IN, is enabled. OSC SEL has a 3 μA internal pull up, (see Table I).
OSC IN	Oscillator Logic Input. With OSC SEL low, OSC IN can be driven by an external clock signal or an external capacitor can be connected between OSC IN and GND. This sets both the reset active pulse timing and the watchdog timeout period (see Table I and Figure 4). With OSC SEL high or floating, the internal oscillator is enabled and the reset active time is fixed at 50 ms typ. (ADM691/93) or 200 ms typ (ADM695). In this mode the OSC IN pin selects between fast (100 ms) and slow (1.6 s) watchdog timeout periods. In both modes, the timeout period immediately after a reset is 1.6 s typical.
